Dr. Horace Hatch died at his home in New Haven, on August 28th, of apoplexy. Dr. Hatch began the practice of medicine in the West, but afterward went to Washington, where he lived upward of twenty years, being one of the most prominent physicians of the city. He retired to New Haven in 1884. He leaves a widow.

The Meeting of the British Medical Association at Bournemouth is pronounced by the English journals an unqualified success, combining, as it did, the maximum of social enjoyment with the maximum of practical work.

Jacques, the Fasting Man, has started in for another long period of total abstinence from food at the London Aquarium.

St. John's Guild Floating Hospital.—The daily trips of the Floating Hospital of St. John's Guild have been continued up to September 5th, and the Seaside Hospital also remained open for the same time. The hospital barge has been making regular trips through the summer, as usual, with the result, doubtless, of saving many a baby's life that would else have been burned out in the hot streets and crowded tenements of a great city.

Dr. Daniel Pardee died of paralysis at his home at Fulton, N. Y., on August 25th, aged sixty-two. He was a son of the late Dr. Stephen Pardee, of Fulton, and father and son were long associated in practice. He was graduated from the Albany Medical College, and served with the Union armies as a surgeon through most of the war. He afterward was pension examiner for the Oswego district. He was a member of the Oswego County Medical Society.

Congress of American Physicians and Surgeons. *Second Triennial Session.*—The Congress meets in Washington, D. C., September 22d to 25th, inclusive. It is composed of the members of those National Medical Societies whose names and Secretaries are given below, and of foreign guests specially invited by the Executive Committee. To enable a physician residing in the United States to become a member of the Congress, with the right to participate in its proceedings, it is necessary that he be a member of one of these Constituent National Societies. A physician may be accredited as a visitor to the Congress by any one of the Constituent Societies. The certificate of the Secretary of one of these societies to the effect that he is thus accredited will enable him to register upon payment of the registration fee, which registration will entitle him to a card of admission to the President's reception and to a copy of the Transactions of the Congress, but not to take part in the deliberations of the Congress. The following are the names of the Constituent Societies in the order of date of their organization, their place of meeting, and the names and addresses of their respective secretaries, to whom inquiries, as to mode of obtaining membership, should be addressed: American Ophthalmological Society, Ladies' Parlor, No. 2, Arlington Hotel; Secretary, S. B. St. John, M.D., Hartford, Conn. American Otological Society, Ladies' Parlor, No. 1, Arlington Hotel; Secretary, J. J. B. Vermyne, M.D., New Bedford, Mass. American Neurological Association, Parlors 182 and 183, Arlington Hotel; Secretary, Græme M. Hammond, M.D., 58 West Forty-sixth Street, New York City. American Gynecological Society, Lecture Hall, Columbian University, 15th and H Streets N. W.; Secretary, H. C. Coe, M.D., 27 East Sixty-fourth Street, New York City. American Dermatological Association, Parlor, The Shoreham; Secretary, George Thomas Jackson, M.D., 14 East Thirty-first Street, New York City. American Laryngological Association, Parlor A, Arlington Hotel; Secretary, Charles H. Knight, M.D., 20 West Thirty-first Street, New York City. American Surgical Association, Main Hall, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; Secretary, J. R. Weist, M.D., 118 North Eighth Street, Richmond, Ind. American Climatological Association, Hall No. 2, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; Secretary, J. B. Walker, M.D., 1617 Green Street, Philadelphia, Pa. Association of American Physicians, Hall No. 1, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; Secretary, Henry Hun, M.D., 33 Elk Street, Albany, N. Y. American Association of Andrology and Syphilology, The Shoreham; Secretary, J. A. Fordyce, M.D, 66 Park Avenue, New York City. American Orthopedic Association, New Reception Room, Arlington Hotel; Secretary, John Ridlon, M.D., 337 West Fifty-seventh Street, New York City. American Physiological Society, Parlor 181, Arlington Hotel; Secretary, H. Newell Martin, M.D., Baltimore, Md. Association of American Anatomists, Hall No. 3, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; Secretary, D. S. Lamb, M.D., 800 Tenth Street, Washington, D. C. American Pediatric Society, Parlor 206, Arlington Hotel; Secretary, W. D. Booker, M.D., 851 Park Avenue, Baltimore, Md.

All physicians are invited to attend the meetings of the Congress and the public meetings of the Societies, but only those may register who are members, specially invited guests, or visitors accredited through the Secretaries of Constituent Societies. The registration office will be in Parlors 1 and 2 of the Arlington Hotel. From this office the mail of members and invited guests will be distributed, and here the city address of each member, guest, and accredited visitor can be ascertained. All members, invited guests, and accredited visitors should register as soon as possible. A registration fee of five dollars will be required of all members and accredited visitors. Invited foreign guests will register, but will pay no registration fee. A copy of the published Transactions of the Congress will be sent to all members, and to each invited guest and accredited visitor who is registered. Only

those who register, and the ladies accompanying them, will be admitted to the reception of the President of the Congress. It is recommended that members effect registration in advance of the meeting by filling out the blank certificates of registration which will be sent to each member about September 10th, and forwarding these certificates, with the requisite fee, to Dr. John S. Billings, Treasurer of the Congress. The sessions of the Congress will be held from 3 to 6 P.M., daily, in the main hall of the Grand Army Building, 1412 and 1414 Pennsylvania Avenue. The President of the Congress, Dr. S. Weir Mitchell, of Philadelphia, will deliver an address Wednesday evening, September 23d, at 8 P.M., "On the History of Instrumental Precision in Medicine." Members of the American Surgical Association and of the Association of American Physicians will conjointly entertain their foreign guests at a dinner at the Arlington Hotel, Thursday, September 24th, at 8 P.M. The American Gynecological Society will give a dinner at the Arlington Hotel, Thursday evening, September 24th. The American Orthopedic Association will give a dinner at the Hotel Arno, Thursday evening, September 24th. The American Laryngological Association will give a dinner at the Hotel Arno, Thursday, September 24th, at 7 P.M. The American Pediatric Society will give a dinner at the Arlington Hotel, Thursday evening, September 24th. The American Dermatological Association and the American Association of Andrology and Syphilology will, conjointly, give a dinner Tuesday evening, September 22d. The American Neurological Association will give a dinner at the Hotel Arno, Thursday evening, September 24th. The American Climatological Association will give a dinner, the time and place to be announced hereafter.

A number of distinguished physicians and surgeons from abroad have accepted the invitation to attend, among whom may be named Mr. B. E. Brodhurst, Mr. Thomas Bryant, Mr. A. E. Durham, Mr. Reginald Harrison, Sir William MacCormac, Mr. Howard Marsh, Dr. William M. Ord, Mr. Frederick Treves, and Mr. U. Pritchard, of London; Mr. Robert Jones, of Liverpool; Dr. W. T. Gairdner, of Glasgow; Mr. E. H. Bennett and Professor J. J. Cunningham, of Dublin; Professor John Chiene and Dr. J. Battey Tuke, of Edinburgh; Mr. G. A. Wright, of Manchester; Dr. F. Beely and Professor H. Krause, of Berlin; Professor Curschmann, of Leipzig; Professor Hoffa, of Wurzburg; M. Emil Javal, Dr. Loewenberg, Dr. Pozzi, and M. Paul Redard, of Paris; Dr. von Mozengeil, of Bonn; and Dr. Rafael Lavista, of Mexico. As other societies will meet in Washington during the Congress week, it will be prudent for members and visitors to secure hotel accommodations in advance.

Officers of the Congress.—S. Weir Mitchell, M.D., *President;* Presidents of Constituent Societies, *Vice-Presidents, ex officio;* William Pepper, M.D., Philadelphia, Pa., *Chairman of Executive Committee;* John S. Billings, M.D., Washington, D. C., *Treasurer;* William H. Carmalt, M.D., New Haven, Conn., *Secretary.*

Committee of Arrangements.—Samuel C. Busey, M.D., *Chairman,* 1545 I Street N. W., Washington, D. C.; John S. Billings, M.D., Army Medical Museum, Washington, D. C.; W. W. Johnston, M.D., 1603 K Street, Washington, D. C.; R. T. Edes, M.D., 1214 Eighteenth Street, Washington, D. C.; S. O. Richey, M.D., 732 Seventeenth Street, Washington, D. C.; J. Taber Johnson, M.D., 1728 K Street, Washington, D. C.; Samuel S. Adams, M.D., 1632 K Street, Washington, D. C.; I. E. Atkinson, M.D., 605 Cathedral Street, Baltimore, Md.; C. F. Bevan, M.D., 807 Cathedral Street, Baltimore, Md.; Samuel Johnson, M.D., 204 Monument Street, Baltimore, Md.; Samuel Theobald, M.D., 304 Monument Street, Baltimore, Md.; H. Newell Martin, M.D., Johns Hopkins Hospital, Baltimore, Md.; D. Forest Willard, M.D., 1818 Chestnut Street, Philadelphia, Pa.; D. S. Lamb, M.D., 800 Tenth Street, Washington, D. C.

Obituary.

ABRAM DuBOIS, M.D.,

NEW YORK.

DR. ABRAM DUBOIS, one of the oldest physicians in this city, and one of the greatest friends to medical science, died at his residence, 16 West Thirtieth Street, on Saturday evening, August 29th. He was a native of Red Hook, Dutchess County, and was eighty-one years old at the time of his death. His collegiate education was obtained in Trinity (then Washington) College, Hartford, where he was graduated in 1830, when but twenty years old. After graduation he entered the office of Dr. Nelson, in Rhinebeck, and later that of Dr. J. K. Rodgers, in this city, while he attended lectures at the College of Physicians and Surgeons. He received his medical degree from that institution in 1835, then studied two years abroad, and on his return entered the Bellevue Almshouse Hospital as interne.

Dr. DuBois was one of the ten living benefactors of the New York Academy of Medicine, and he richly deserved this title. Visitors to the old building were familiar with the tablet in the main hall which read: "This Hall, the Gift of Abram DuBois, M.D., a Generous Benefactor of the New York Academy of Medicine, was Erected A.D. 1879." But this was by no means the extent of his donations, for it is largely owing to his gifts of money and books that the library is what it is. He not only gave $3,000 for a permanent library fund, and presented the Academy with many bound volumes, but also gave the librarian *carte blanche* to purchase any new books that might be needed and send the bills to him, contributing about $1,500 more in this way. Upon the erection of the new building the tablet was transferred from the old hall and placed in one of the rooms of the Academy, known as the DuBois room.

Dr. DuBois was identified for over forty years with the New York Eye and Ear Infirmary, having been appointed Assistant Surgeon there in 1843, and then serving as Surgeon and Consulting Surgeon, and later as Trustee and Vice-President of the Board of Directors. He was also actively interested in many of the charitable institutions in this city. He was one of the founders of the New York State Medical Association and of the New York County Medical Association, a member of the New York Medical and Surgical Society, of the Physicians' Mutual Aid Association, and of the American Ophthalmological Society, benefactor of the Society for the Relief of Widows and Orphans of Medical Men, Consulting Physician to the New York Institution for the Blind, to the Northern Dispensary, and to the Home for Incurables, and a member of various other associations in New York.

Few men have done more to advance the interests of the medical profession in New York than Dr. DuBois, and his memory will remain ever dear to those who knew him in life, while his name will live always in the medical and charitable annals of this city.

Society Reports.

SECOND CONGRESS FOR THE STUDY OF TUBERCULOSIS.

Held in Paris, July 27, 28, 29, 30, and 31, and August 1, 1891.

(Special Report to the MEDICAL RECORD.)

(Continued from page 239.)

FOURTH DAY, THURSDAY, JULY 30TH.

IN the morning of this day the members assembled at Val-de-Grâce, where M. BURLUREAUX presented a number of patients whom he had treated by his method of subcutaneous injections of creasote in large doses. The injections seemed also to have a very beneficial influence upon malarial paroxysms, for some of his patients returning from Tonkin with tuberculosis were also suffering severely from intermittent fever, and this disappeared after the injections had been begun.

Hospital Treatment of Tuberculosis.—The discussion of this question was opened by M. LEROUX, who reported upon the results obtained in hospitals for tuberculous children established at the seashore. The results had everywhere been excellent, and the number of beds in institutions of this sort in France now was upward of 1,700. The benefits were in proportion to the length of stay of the little patients in the hospitals. In those institutions in which the children were received for a short time only the percentage of cases cured or markedly improved was only a little over twenty-five, while in those in which the patients were detained a long while, not less than from seventy to ninety per cent. were benefited.

M. VIDAL was in favor of short treatment, or rather of intermittent treatment. He would have the patients spend a short time at the seashore, just long enough to let them get saturated, as it were, with the sea air, then he would remove them for a while and bring them back for another saturation.

M. ARMAINGAUD was wholly opposed to this intermittent treatment, and thought the correctness of his view was well substantiated by his experience at Arcachon, where the children were detained for long periods, and continued to improve steadily.

M. PETIT described the hospital for tuberculous children at Ormesson, which had been opened in 1888 with twelve beds and now had one hundred. The hospital was free, and the extent of the work was increasing constantly.

Surgical Treatment of Pulmonary Cavities.—MM. POIRIER and JONNESCO read a paper upon this subject, based upon their experiences in twenty cases. Their mode of operating was as follows: An incision through the skin and subcutaneous tissue, made by the thermo-cautery, is carried from a point in the middle line of the sternum, two fingers' breadth below the notch, along the first intercostal space for a distance of 9 ctm. The pectoralis major now appears at the bottom of the incision, and by means of a sound some natural separation in the fibres of this muscle is exaggerated until the intercostal space beneath is exposed. The intercostal muscles are then carefully divided and the pleura exposed. If this is found to be adherent, as it usually is in the cases in question, the cavity is at once widely opened by the thermo-cautery. When the pleura is non-adherent a slight inflammation must be provoked, further operation being postponed for a few days. The operation is easy of accomplishment, and is free from danger. Resection of the ribs is unnecessary, drainage, disinfection, and local medication being easily accomplished without it. In twenty-nine cases of incision into pulmonary cavities there had been four cures, fifteen in which there was more or less benefit, both local and general, nine without result, and one the result of which was not known. The authors urged the more frequent employment of this method of treatment in pulmonary phthisis in which cavities had formed.

Systematic Ventilation of the Sick-room.—M. DUBRANDY read a paper on the advantages of continuous aëration of the bedroom occupied by a phthisical person. The patient should sleep with a window open at the foot of the bed, they themselves being well wrapped up and having their heads covered. He had seen the disappearance of the cough, night-sweat, and morning vomiting as a result of the institution of this free ventilation of the sleeping apartment.

High Altitudes in the Treatment of Tuberculosis.—M. PETIT read, in behalf of an absent member, a paper describing his mode of treatment of tuberculous patients at a mountain resort during the winter.

Toxic and Vaccinal Substances Contained in Cultures of Tubercle Bacilli.—M. BABÈS read a paper embodying the results of a study which he had made of these substances. They were dialyzable and were precipitated by alcohol, and were without doubt albuminoids. They were incapable of producing the disease, differing in this respect from the products of culture of tetanus and diphtheria bacteria. Certain substances obtained from aviary cultures resembled in some respect those found in human cultures, but the speaker would not conclude from this that the bacilli were identical.

Inoculation with Lupus Vulgaris.—M. LELOIR presented a communication in which he gave the results of the inoculation of guinea-pigs and rabbits with portions of tissue from lupus. The development of tuberculosis in animals took an average of about three weeks, and by the end of four months it was found fully established. In order to succeed, however, it was necessary to introduce the material into the anterior chamber of the eye, in the rabbit, and into the peritoneum in the guinea-pig, and a comparatively large piece had to be used. All attempts to produce the disease by introducing the lupus tissue under the skin of the animal were unsuccessful, thus proving that the virulence of this form of tuberculosis was slight.

M. NOCARD had obtained very similar results in the inoculation of rabbits with hog scrotula.

Spontaneous Tuberculosis in a Dog.—MM. CHANTEMESSE and LE DANTEC reported a case of tuberculosis occurring in a dog. The tumors had the appearance of sarcomata, but bacteriological examination and the result of inoculation showed the presence in them of tubercle bacilli. It is incorrect, therefore, to regard the dog as immune from tuberculosis. The authors thought that this opinion had arisen from the fact that tubercular lesions in this animal resembled sarcoma so closely.

M. ARLOING said that he had not made any particular study of lupus, but from his investigations into other forms of tuberculosis he had no doubt but that there were many varieties, differing greatly in their degree of virulence, according to the degree of attenuation of the bacilli.

Treatment of Tuberculosis of the Testicle.—M. HUMBERT read a paper on this subject in which he expressed himself as wholly opposed to castration. If the epididymis and testicle were both extensively involved he would still not castrate, but would scrape out all the diseased tissue with the curette, resecting the epididymis if necessary. There would be left the thickened tunica vaginalis, and after cicatrization there is to be felt a rounded body giving the appearance of a testicle, and which M. Verneuil had very happily called a "moral testicle."

M. VERNEUIL said that he had for many years condemned castration in this disease, an operation which not infrequently was the direct apparent cause of a generalization of tuberculosis. But in any case castration is useless, as we do not thereby remove the only focus of disease, the prostate and vesiculæ seminales being also affected in at least eighty per cent. of these cases.

Gastric Conditions in Tuberculosis.—M. Marfan read a paper on this subject, which he regarded as one of prime importance, since the necessity of proper nutrition of the patient with phthisis was so apparent. The dyspepsia of this disease usually appeared quite suddenly, but sometimes there were prodromic symptoms extending over a longer or shorter period, consisting in more or less gastric pain and hyperacidity. Accompanying this is dilatation of the stomach. In the later stages of the disease this ordinary dyspepsia sometimes gives place to actual gastritis. The treatment of the dyspepsia of the phthisical should follow no fixed rule, but should meet the indications furnished by each particular case.

M. Tuffier said that the surgeon was often embarrassed to decide whether a hydrocele which he was called upon to treat was due to the presence of tubercles in the tunica vaginalis or not. In order to determine this point he was accustomed to inoculate animals with the fluid withdrawn. Bacteriological examination of the fluid is usually negative, but intra-peritoneal injection will give certain results if the fluid depends upon the presence of a tubercular lesion.

Inoculation of Tuberculosis through Vaccine Virus.—M. Bernheim reported the results of experiments which he had made to determine whether bovine virus ever contained tubercle bacilli, and whether vaccination could give rise to tuberculosis. His conclusions were that vaccination was in general inoffensive, but that it would be better always not to employ any bovine virus for vaccinations, until the vaccinifer had been killed, and had been shown by post-mortem examination to be free from any tuberculous lesions. He added also that he had made use of goats' blood in preference to dogs' in the treatment of tuberculosis, for the reason that the dog was subject to rabies.

M. Nocard said this was a purely imaginary danger, for the blood of a mad dog never contained the virus of the disease, or at least it had been found impossible to produce the disease by means of inoculations with the blood.

Retro-Malleolar Tuberculosis.—M. Clado read a paper on this condition, which he said was not rare, but was of short duration, seldom remaining localized for any protracted period. At its inception it often simulated a gumma.

Tuberculosis and Malaria.—M. Kohos had studied in Tunis the relations existing between malaria and tuberculosis. He had found that those profoundly under the influence of the malarial poison frequently became the subjects of tuberculosis, and he believed that the anæmia associated with malaria was a predisposing cause of tuberculosis. In grave cases of pernicious fever transfusion of blood was indicated, not only to remove the immediate danger to life, but also to overcome the anæmia on account of which an invasion of tuberculosis was threatened.

Heating in Tuberculous Arthritis.—M. Clado related some attempts to destroy the bacilli in tuberculous joints by exposing the limb, wrapped up in cotton, for some time to a temperature of 230° F., which he said could be borne. Of six cases of tuberculous ostitis of the ankle and wrist treated after this plan four were cured and two markedly benefited.

Fifth Day, Friday, July 31st.

Prophylaxis of Tuberculosis.—The discussion of the fourth question was opened by M. Arloing. He said that objection had been made to the prohibition of the flesh of tuberculous animals as food for man, on the ground that the identity of human and bovine tuberculosis had not been established. But he denied this, and said that the identity had been established by experiments sufficiently to warrant the strictest measures to prevent the consumption of flesh from tuberculous animals. It had also been maintained that cooking removed all danger, but he held that there was no certainty that the danger was overcome unless the meat was very well done. He estimated the number of tuberculous animals that ought to be destroyed at five per cent. of the total number butchered.

M. Nocard thought that the previous speaker had put the percentage of tuberculous animals much too low, and thought that, if the owners of diseased animals were recompensed for their loss, the number would be found to be considerably greater than it is now supposed to be, for the owners will naturally do all they can to prevent the discovery of the disease in their stock.

M. Trasbot said that, if the inspection of beeves were to be made properly, it would be necessary to suppress all private abattoirs, and allow no animals to be slaughtered except in public abattoirs. The cost of slaughtering is furthermore cheaper in the latter than in the former.

The question was further discussed by MM. Butel, Laquerrière, Robcis, and Degive.

M. Espina y Capo presented a communication in which he urged the isolation, as far as practicable, of tuberculous patients, destruction by fire of sputa and fæces, and of the clothing and personal effects of a nature likely to hold the germs. The children of tuberculous mothers should not be allowed the breast milk, but should be put out to nurse or should be fed artificially. Young persons with a predisposition to disease should early be taught to practise respiratory gymnastics. No milk should be taken that has not been previously boiled, and all meats should be most thoroughly cooked.

M. Verneuil said that when one was called to see a pregnant woman who was syphilitic, measures were at once taken with a view to preserve the child from infection if possible, but this was never done in the case of tuberculosis. He urged that as much attention be given to the tuberculous woman as had always been bestowed upon the syphilitic.

Alcohol in the Etiology of Tuberculosis.—M. Tison read a paper on this subject. After alluding briefly to the ill effects of damp and dark dwellings, poor food, etc., he said that enough attention had not been given to the influence upon the development of tuberculosis exerted by the immoderate consumption of alcoholic liquors. The man who drank habitually more than a bottle of wine a day was in danger of becoming dyspeptic, this would lead to more drinking, gradually the strength would be lost, and the individual would then offer a proper field for the reception and development of the tubercle bacilli. The speaker related a number of cases of drunkards who became tuberculous, and he said this was a question of the most urgent moment, especially in cities.

M. Arthaud presented a number of statistics showing the excessive frequency of tuberculosis in certain infected localities. He called especial attention to the danger to healthy individuals of remaining for any length of time in watering-places and health-resorts frequented by the phthisical. He advocated a law requiring the physician to report all deaths from tuberculosis, so that the authorities might take measures to disinfect thoroughly the dwelling occupied by the patient.

M. Bouland sent a communication calling attention to the influence of the inhalation of kaolin dust in provoking pulmonary disease among the operators in porcelain factories. The irritation caused by the lodgement of the dust afforded a nidus for the tubercle bacillus, but the progress of the disease was always very slow, for the same irritation that furnished a proper soil for the bacilli also excited a sclerosing process which limited the further spread of the lesion.

Koch's Lymph in Cattle.—M. Cagny read a paper, giving the result of a number of experiments made upon cattle with tuberculin. Thirty animals were bought in the market, and were given injections of tuberculin, and then very carefully watched by several skilled veterinarians, who made regular thermometric observations. A febrile reaction was noted in only four of the animals, and these

four were found, when all the animals were killed, to be the only tuberculous ones in the herd.

A Prize of Six Hundred Dollars. — M. Verneuil announced that a prize of 3.000 francs would be awarded at the next congress to the author of the best essay on "The Best Means of Diagnosing Latent Tuberculosis."

Sixth Day, Saturday, August 1st.

Means of Destroying the Tubercle Bacillus.—The fifth question proposed for discussion was that of agents capable of destroying the bacillus of Koch, which at the same time are not injurious to the human organism.

M. Diamanterberger read a paper concerning the subcutaneous injection of guaiacol in the treatment of tuberculosis, based upon the experiences of M. Weil and himself. They employed a fifty per cent. solution of guaiacol in sterilized oil of sweet almonds, injecting on an average two Pravaz syringefuls in the twenty-four hours. They had made more than ten thousand injections, and never had an accident.

M. Desprez presented a communication on the use of chloroform as an anti bacillary agent. He said that it was an efficient microbicide, and being volatile, could be readily introduced into the air-passages.

M. Picot spoke of the method already published by him of injection of guaiacol and iodoform in sterilized oil and liquid vaseline, and related several cases in which much improvement in the general and local conditions had followed the use of these remedies. He did not claim that this method constituted a specific for tuberculous disease, but it was often of very great service

Typho-Bacillosis.—M. Landouzy read a paper on a form of disease which clinically bore a striking resemblance to typhoid fever, the only characteristic symptom that was absent being the rose colored spots. On autopsy, however, the lesions of typhoid fever are not found, but instead the presence of young miliary tubercles is noted. He had first called this disease typho-bacillosis, but now proposed the name of pretuberculous bacillary fever.

Hæmatoscopy in the Study of Tuberculosis.—M. Hénocque read a paper detailing the results of numerous spectroscopic examinations of the blood of tuberculous individuals. In all cases the oxyhæmoglobin was reduced in quantity, the reduction being in general in proportion to the gravity of the lesions and to the depressed condition of the patient, though it was always most marked in tuberculosis of the bones and joints, and least marked in lupus. In regard to the therapeutics of the disease, one of the author's deductions from his investigations was that arsenic and iron were very efficacious, at least in so far as they tended to increase the proportion of oxyhæmoglobin in the blood.

The Sclerogenic Method.—M. Coudray read a paper on "Lannelongue's Method of Treating Surgical Tuberculosis by Injections of Chloride of Zinc," and described its application in a case of Pott's disease.

The Diagnosis of Tubercular Testicle.—M. Tuffier described a method used by him to determine whether a hydrocele was simple in its nature or symptomatic of tuberculosis of the testicle. This consisted simply in injecting some of the fluid into the peritoneum of a rabbit. This was much more certain than a bacteriological examination of the fluid.

M. Petit delivered an address at the close of the session, and then, after the adoption of a number of resolutions relating to public measures for the prevention of tuberculosis, the Congress was declared adjourned.

Gonorrhœal Rheumatism in a Young Child.—Dr. Auguste Ollivier reports in *La Médecine Moderne*, of June 25, 1891, a case of gonorrhœal rheumatism observed in a girl five years of age.

THE INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

Held in London, August 10, 11, 12, 13, 14, 15, 17, 1891.

(From our Special Correspondent.)

First Day, Monday, August 10th.

The opening meeting of the Congress was held in the afternoon in St. James' Hall. About two thousand persons were present. Sir Douglas Galton presented the Report of the Permanent International Committee. The Prince of Wales, President of the Congress, then gave a short address in which he tendered a hearty greeting to all the members.

Speeches were then made by the following foreign members of the Congress on behalf of the countries they represented, viz., Dr. Brouardel (France), Dr. Van Coler (Prussia), Professor Corradi (Italy), Dr. Roth (Germany), and Professor Körösi (Austria-Hungary). Sir James Paget then moved a vote of thanks to the Prince of Wales for having accepted the office of President, and for the manner in which he had conducted the business of the day. This was seconded and carried unanimously.

Second Day, Tuesday, August 11th.

SECTION ON PREVENTIVE MEDICINE.

Advance in Preventive Medicine.—Sir Joseph Fayrer presided and gave an interesting introductory address. He spoke of the present aspects of preventive medicine, its recent development, and of how the public mind was becoming gradually imbued with the conviction that prevention was better than cure, and often easier. The advance in preventive medicine had been most remarkable during the last half of the present century. It was now pretty generally understood that about one-fourth of all the mortality in England was caused by preventable disease, that the death rate of large communities might be reduced much below that at which it was wont to stand, that the average duration of life might be made to approximate near to the allotted four score, and that the conditions of living might be greatly ameliorated. Certain well-known diseases were less severe now, if not less frequent. The death-rates from small-pox, enteric fever, typhus, and scarlatina, had declined of late years; that from diphtheria had increased, showing, perhaps, that the disease was now better differentiated from scarlatina. Dr. Buchanan, in England, and Dr. Bowditch, of Massachusetts, had both showed that there was a striking parallelism between the diminution of the death rate from phthisis and the drying of the soil resulting from the construction of sewerage works. Preventable disease still killed in England about 125,000 yearly, and it had been calculated that 78¼ million of days of labor were lost annually from preventable sickness, which meant $39,000,000 per annum. It was not to be expected that we could exterminate zymotic disease altogether, but we could diminish its incidence. The speaker was inclined to give a very wide scope to preventive medicine. The records of the past fifty years proved the influence exerted by sanitary measures on vital statistics. The beneficial results of sanitary work were also well illustrated in India. In preventive as in curative medicine, knowledge of causation was essential, and recent advances in physiology, chemistry, histology, and pharmacology had done much to throw light on the nature and causes of, and also on the means of preventing or of dealing with, disease. The study of bacteriology was opening out sources from which might flow results of incalculable importance in their bearing on life and health.

The Mode of Preventing the Spread of Epidemic Disease from one Country to Another.—Surgeon General Cunningham then read a paper on this subject. Taking cholera as the type of epidemic disease, he said we had three well-recognized methods of preventing its spread

from country to country, viz. : 1, Quarantine; 2, medical inspection; 3, sanitary improvement. Land-quarantine was impracticable, and sea quarantine had done no good. The liability of the inhabitants of Malta to all epidemics was a good example of the failure of sea-quarantine to effect practical results. Medical inspection of those entering a port was of some merit, and certainly the sick benefited by it, but the third method was the only one of real service.

The Transmission of Cholera from one Country to Another.—Inspector-General Lawson read a paper on the above subject. He said there had been, and still remained, a most serious error in assuming that personal communication was so powerful a factor as many believed. The speaker related three instances which had occurred of late years, of the outbreak of malignant cholera at points in advance of those which the disease had already reached in the epidemic form. These instances showed that the efficient factor of cholera could be conveyed by atmospheric currents, from where it was already prevailing to localities at a great distance, in sufficient quantity to generate an epidemic. Cholera, therefore, could not be excluded from any country by quarantine, and all that could be done was by hygienic measures to improve the health of the population, and to remove the conditions favoring the formation of foci.

Australian Quarantine.—Dr. Ashburton Thompson read a paper on this subject. The views accepted in Australia, he said, were based on the resolutions passed at the Australasian Sanitary Conference held at Sydney in 1884. Medical inspection was the outcome of England's local conditions, was exactly suited to them, and therefore not necessarily suitable where local conditions differed from England's. The degree of protection which quarantine could afford varied inversely with the ease of communication between the infected country and the country to be defended. Quarantine could yield protection commensurate with its cost only in countries whose internal sanitation was good, and its function was not to exclude infection, but to lessen the entering number of the foci of infection. The author then proceeded to point out that nations whose internal sanitary organization was not perfect could not afford to refer the observation of suspects to the country at large. Consequently, limited quarantine should be employed against ships actually carrying cases of exotic disease—that is, vessels and equipment should be cleansed forthwith—but the ship's company should be detained in isolation for periods slightly in excess of recognized incubation periods.

A discussion followed the reading of these papers. Dr. Felkin, of Edinburgh, gave an account of the preventive methods in use among some of the White Nile tribes. Certain African tribes had actually stamped out syphilis by methods of inoculation closely allied to our vaccination. Cholera, to Dr. Felkin's knowledge, had penetrated as far as Uganda and Uynoro, and there the natives recognized the value of preventive methods. On the last occasion they not only evacuated but burnt their villages, with the result that the disease was arrested.

Dr. Simpson, of Calcutta, said everything went to prove that there was no danger of cholera being brought to Europe by sea. India had been considered to be the starting-point of cholera, but India had three populations —the Hindoos, the Mohammedans, and the Europeans. The Europeans who travelled were not very subject to cholera; the Hindoos, who were immensely subject to cholera, did not travel at all, because they would lose their caste. Mohammedans were the real danger, and Mecca or Medina might be looked upon as a permanent threat to European security.

Dr. Hewitt, of Minnesota, said quarantine and medical inspection might do much, but not unless they were properly organized.

Le Duc, of Nantes, Professor Brouardel, and several others then spoke of the practical good to be obtained from a system of strict quarantine.

Sir Joseph Fayrer remarked that he was in entire accord with all the ordinary hygienic notions of the French, but he could not think their notions about the efficacy of quarantine were serviceable.

Dr. Stokvis, of Amsterdam, spoke favorably of English sanitary measures in India, and Dr. Robert Pringle brought the discussion to a close by expressing his concurrence with the opinion expressed by Surgeon-General Cunningham, as to the uselessness of quarantine.

SECTION ON BACTERIOLOGY.

Etiology of Malaria.—The first paper was read by Professor Laveran, of Paris, on "The Etiology of Malaria." He said that the hæmatozoon described by him in 1880 had since been recognized by many other observers. He described the chief forms which it assumed, viz., spherical bodies, flagella, cruciform bodies, and rosette shaped bodies. There were also deeply-pigmented leucocytes to be found in the blood of patients suffering from malaria. The flagella could only be demonstrated in fresh blood; the other forms were well seen in preserved blood. Similar hæmatozoa had been found in different animals—frogs, lizards, marsh tortoises, and birds, yet several points of difference existed.

Professor Crookshank congratulated Professor Laveran on his paper, and said the evidence was in favor of the bodies described by M. Laveran being the cause of malaria; but it must not be forgotten that they were also found in healthy animals.

Mr. W. North said there were, no doubt, peculiar changes to be seen in malarial blood, but he could not believe that malaria was due only to these changes. The plasmodium had never as yet been discovered in air, earth, or water, and no results had ever been obtained by the injection of undoubtedly malarial soil.

Asiatic Cholera and the Comma Bacillus.—Professor Hueppe, of Prague, then read a paper on the above subject. He described the cultivation of the bacillus in different media and under various conditions. He had been able to produce death in the lower animals, which was an advance on Koch's researches.

Dr. Klein said he did not think comma bacilli always occurred in sufficient numbers to produce cholera, and uniform numbers of bacilli were not always present in cholera.

Dr. Cunningham, of Calcutta, said he had found eight different species of comma bacilli. Comma bacilli were also found in the mucoid tissue of healthy apes and guinea-pigs.

Professor Max Gruber, of Vienna, considered that it was almost proven that the comma bacillus was the cause of cholera, though in some minor points he had not obtained the same results as Professor Hueppe had.

Dr. Bruce, of Netley, said that he had injected a pure culture of cholera bacillus into guinea-pigs, and they died; rats similarly treated did not die. He had found comma bacilli grew well inside eggs, and described some experiments he had performed with egg cultivations.

The Mouth as a Focus of Infection, was the title of a paper read by Professor Miller, of Berlin, in which he enumerated the local and general diseases—thirty-five in number—due to the action of bacteria in the mouth, and gave a list of these pathogenic bacteria. In inoculating animals with the saliva of one hundred and eleven healthy persons, death followed in one hundred and one cases. Two groups of pathogenic bacteria occurred in the mouth, one producing speedy death through septicæmia, the other producing extensive suppuration. The value of antiseptic solutions in prophylaxis was then discussed.

The Bacteriology of Dental Caries.—Mr. Henry Sewill then read a paper on this subject. The active agents in caries, he said, were acids and micro-organisms. As predisposing causes he enumerated, (1) inherent de-

fects in enamel, (2) crowding or irregularity of the teeth. (3) vitiated buccal secretions.

Professor Gruber described a new pyogenic micro-organism—micromyces Hoffmanni—and Professor Crookshank gave an account of his observations on streptococcus pyogenes, which had led him to conclude that distinct varieties of the organism existed.

Cancer as an Infective Disease.—Messrs. Shattock and Ballance contributed the above paper. They maintained that cancer ought to be regarded as a parasitic disease, though it had not yet been found possible to transmit cancer from one species of animal to another, and all attempts at cultivating a microbe had failed as yet. Cancer had, however, been transferred from one rat to another, and from dog to dog.

Psorospermosis as a Possible Cause of Epithelial Tumors.—Dr. Sheridan Delépine read a paper on this subject. He concluded that the evidences which he had been able to collect were against the psorospermial nature of the bodies which he had observed in epithelial tumors, and he thought the same conclusions must extend to the bodies observed in Paget's disease of the breast.

SECTION ON THE RELATION OF THE DISEASES OF ANIMALS TO THOSE OF MAN.

Dr. Roux, of Paris, delivered an address on "The Prevention of Hydrophobia," and gave an account of the results obtained in the Pasteur Institute.

The Prevention of Rabies in Dogs was the title of a paper read by Dr. George Fleming. He urged that the following measures should be adopted, viz.: 1, the destruction of rabid dogs; 2, the control of ownerless dogs; 3, muzzling; 4, dog tax and registration. The value of the muzzle in suppressing rabies had been especially demonstrated in London in 1885. In other countries where rabies prevailed, and dogs were not muzzled, though other measures—as the dog tax, medal on the collar, leading by a leash, etc.—were adopted, the malady continually manifested itself, and numbers of people perished from hydrophobia every year.

M. Nocard, of Alfort, spoke of a prophylactic treatment which he thought applicable to domestic animals, at least to herbivora. M. Galtier announced some time ago that the injection of rabic virus into the veins of the sheep and the goat did not produce hydrophobia, but rather conferred immunity. He had himself made a number of experiments recently, by which he had been able to show, 1, that the intra venous injection of rabic virus would not produce rabies in horses; 2, that if the quantity injected was sufficient, these horses acquired an immunity against rabies; 3, that it was possible to protect equines inoculated by intra-ocular injection when there were introduced into the veins certain quantities of dilute rabid nervous material. He hoped a prophylactic treatment might arise out of the labors of M. Galtier.

Professor Redfern, of Belfast, thought muzzling in certain areas only was ridiculous.

Dr. Ostertag, of Berlin, said that in Berlin all dogs wore muzzles, and a case of hydrophobia had not been reported for ten years.

SECTION ON INFANCY, CHILDHOOD, AND SCHOOL LIFE.

The Scientific Observation and Study of Children in Schools.—Dr. Francis Warner read a paper on the above subject. The paper was based upon observations made on fifty thousand children. He had observed that a large percentage of irregular attendance was due to physical weakness. Low nutrition appeared to be largely dependent upon conditions of low development. A class of children presenting certain nerve-signs were ill-balanced and over-mobile, but were usually mentally bright; certain other mental signs were ordinarily associated with low mental status. Eye affections were very numerous, and ophthalmia in all stages was present in some day schools.

Dr. Jacobi, of New York, suggested that feeble-minded children should be trained apart.

Mr. Noble Smith said he had noted a large amount of physical deformity among the working classes in all parts of London, which he attributed to bad nutrition during childhood.

The Early Recognition and Probable Arrest of St. Vitus's Dance in School Children.—Dr. Sturges read a paper with this title. He said the disease was first detected by observation of the muscles of the face, which twitched; then, if the child became ill-tempered and untidy in his appearance, inquiries should be made of the mother if the child slept well and had sufficient food. The chief causes of chorea arising in the school itself were examinations, unexplained sums, and punishment before other children. If there were any muscular infirmity the hand test was infallible. If the child could hold up both hands straight with the fingers open, and there was no falling back of the hands nor quivering of the muscles, he was free from any danger of chorea.

Dr. Cheadle remarked that there was another cause besides the wear and tear of learning and nervousness, and that was excitement. He did not agree with Dr. Sturges as to chorea not being a grave disorder.

Ringworm in Elementary Schools.—Mr. Malcolm Morris read a paper with this title. Ringworm, he said, was very common in London, and he lamented that there was no uniform method adopted in board schools in regard to it.

Dr. Colcott Fox said there were three alternatives for the stamping out of ringworm in schools, viz.: 1, to place affected children in isolated schools; 2, to admit them to schools, but place them in a separate room; 3, to isolate them on separate forms, germicides being applied to the scalp, and a cap worn during school hours.

Epidemics in Schools.—Dr. Shelly, of Hertford, read the above paper. He pointed out that such epidemics usually originated outside schools and were favored by the aggregation of susceptible material.

SECTION ON CHEMISTRY AND PHYSICS IN RELATION TO HYGIENE.

Sir Henry Roscoe presided, and gave an address in which he touched on the water-supply of cities, the disposal of excreta, air pollution, etc.

Town Fogs was the title of a paper read by Dr. W. J. Russell. Fogs acted injuriously mainly in two ways: 1, by the stoppage of light; and 2, by the toxic effect produced by the impurities retained in them—chiefly sulphurous acid and empyreumatic products of carbonism. The author advocated the abolition of fogs by suppressing heating by means of coal.

Fog in Relation to Health.—Dr. Theodore Williams said he believed London fog was not so fatal as many people had supposed, and he had found that some cases of bronchitic asthma were benefited by exposure to it.

Mr. Ernest Hart remarked that the mortality of London during the previous great fogs had been as great as during a cholera season.

A resolution was adopted requesting the proper authorities to consider whether legislative measures could not be introduced to lessen the amount of smoke produced from dwelling houses in towns, and thus diminish the density of town fogs.

Dr. Sheridan Delépine and Mr. A. B. Gomess exhibited an apparatus designed to show the possibility of removing the smoke of fires from the air of towns, and of using it for disinfecting sewers. By means of a small amount of water falling a few feet, a large amount of air could be displaced, and the smoke of a fire from a chimney diverted into a system of pipes running in any direction, and by a very simple combination of channels

and chambers the sewage itself might be used for the purpose of displacing the smoke and causing it to mix with the sewage.

SECTION ON NAVAL AND MILITARY HYGIENE.

The first paper read was on "Modern Quarantine in Canada and the United States," by DR. MONTIZAMBERT, Medical Superintendent of the Canadian Quarantine Service.

DR. VALENTIN VIGNARD discussed the relative value and inconveniences of quarantine and medical inspection. In quarantine the dominant idea was isolation; in medical inspection it was disinfection. The progress of international sanitary prophylaxis demanded that disinfection should occupy a more prominent place, and he hoped the word quarantine might pass out of use.

DR. STOPFORD TAYLOR pointed out the want of system in the medical supervision of the mercantile marine in Liverpool.

DR. BÉRANGER-FÉRAUD said that though quarantine was retained, France had not failed to follow the advance of scientific knowledge, and the period of detention of suspected ships or persons was governed accordingly.

DR. MASON, of Hull, described the precautionary measures adopted with emigrants passing through Hull, to the number of forty thousand or fifty thousand annually, *en route* for America.

(To be continued.)

Correspondence.

ATONY OF THE LOWER SEGMENT OF THE UTERUS.

To the Editor of the Medical Record.

SIR: In your issue of July 4th, Dr. W. H. Johnston writes of "A Rare Condition of Labor," giving few details and no specific name to the condition; and desires to know: "Why did not the os uteri dilate?" Among my notes I find a case similarly interesting, of which the following is a synopsis:

Mrs. G——, aged twenty-eight, a primipara, a strongly built little woman, was in labor at term. It was 5 P.M. when I saw her. She had had pains all day, and thought she must be near the end of her suffering. During a pain, which recurred every ten or fifteen minutes, the uterus, as felt through the abdominal wall, seemed to contract powerfully and effectively. Vaginal examination discovered a bag-like protrusion into the vagina from above. It felt thin and fluctuating, and became more tense and protruding with each contraction of the fundus uteri. The waters had not yet escaped. Hastliy assuming this bag to be the amnionic sac, I searched for the margin of a fully dilated os uteri, but could not find it. The bag and the vaginal wall were continuous. The question then arose, was it a case of occlusion of the vagina, or of the os uteri? It was neither, for the length of the vagina was not curtailed, though the os and cervix were seemingly absent; and a more diligent search during a pain discovered a dimple, situated posteriorly toward the sacrum, which proved to be the permeable os uteri. Pressure on the site of this dimple easily effected the entrance of the index finger into the bag, which yielded readily to forward traction by the finger hooked in the anterior segment. The contractions of the fundus seemed to have no effect on the vaginal portion of the uterus, beyond distending it into a protruding bag. The further dilatation was accelerated by Barnes's bag. After several hours' further delay, the pains proving inefficient, forceps delivery was resorted to. The child was found to have a spina bifida sac which had ruptured. Of course the child was still-born. The mother made a good recovery. After the ease with which the os was dilated, it cannot be said there was any rigidity. Hence the only condition I could bring to my aid in explanation of this unusual circumstance was: Atony of the lower segment of the uterus.

Yours truly,

J. J. E. MAHER, M.D.

213 WEST TWENTY-THIRD STREET.

A USEFUL OBSTETRICAL SUPERSTITION.

To the Editor of the Medical Record.

SIR: Some time since the writer was chatting with a well-known practitioner of this city, who said, "There are two classes of patients who will beat you out of your fees whenever they can—fellows with venereal disease and parents with babies. I have lost about as much from cases of labor as from any other class."

As the writer has a small practice in obstetrics, he pondered upon the remark of his confrère and sought a proper remedy for the disease. A case for treatment soon presented itself in the persons of two plausible parents, who sought the writer because they "had heard of his skill, and had been strongly advised by their friends to come to him," etc. Taking it all in, the writer consented to deliver the mother.

Night of delivery, all things *secundum artem*.

"Doctor, it is not quite convenient to pay you tonight, but if you will kindly wait for a week, it will be all right then." "Oh, certainly, it will be quite as convenient then, for I never lose any money on my obstetrical cases." "Indeed, how so? Why not?" "Oh, because it is getting to be a well-established superstition, based upon facts, that 'Parents who allow their baby boy to start in life with a debt on his head the first thing are sure to have a ne'er-do-well, shiftless son, and the little baby girl is sure to marry a dead-beat.'" A peculiar expression came over the father's face, and the mother gave an anxious, wandering look at her baby. Half the bill was paid at the next visit and the rest soon after.

The writer is careful to repeat this obstetrical superstition whenever he can, and always to prompt paying patients, who are congratulated that nothing of the sort awaits their little one. These are the ones who spread the good news.

G. E. A.

VACCINE LYMPH IN TUBERCULOSIS.

To the Editor of the Medical Record.

SIR: An article by J. Hilgard Tyndale, M.D., published in the MEDICAL RECORD for July 18th, renews a hope that I have long felt, that the above agent might find its proper place in the therapeutics of pulmonary tuberculosis. Some two years since [it was in the issue of April 24, 1886.—ED.] I called the attention of the readers of the MEDICAL RECORD to this subject, and about the same time wrote to the late E. Darwin Hudson, M.D., detailing some cases treated, and urging him to experiment in his ward in the Bellevue Hospital. So far as I now know, vaccine lymph was first used for the above purpose by my brother, H. W. Taylor, M.D., now of Anderson, Ind. We jointly performed about fifty inoculations between the years 1876 and 1880 with varying success. The majority of these cases were decidedly benefited thereby—some permanently, others for a longer or shorter period. My brother was very firmly persuaded of the virtues of this agent, ranking it higher than any other. On his abandoning practice a few years after the date mentioned, active experimentation ceased; largely on account of the criticism it met with at the hands of those practitioners who continue the ordinary routine treatment with the usual results, and who fail not to hold up their hands in horror in the presence of such empiricism, regardless of the fact that the remedy heretofore the most potent in the treatment of tuberculosis is a purely empiric one, and regardless also of the fact that

the desperateness of the malady justifies any treatment that promises cure or a prolongation of life. I own that the reason given above for limiting my investigations is not such as challenges much respect; but I have long since recognized the fact that my fibre is not such as martyrs are made from, and, like the great majority, I prefer to sail over smooth seas and before gentle winds, rather than to buffet with white caps and roaring tempests. In spite of opposition, however, I have continued to use the vaccine lymph, in carefully selected cases, down to the present time.

Formerly we used the lymph in the ordinary manner; but of late I have used it hypodermically. When it "takes," in the characteristic manner, it scarcely ever fails to produce a change for the better, more or less pronounced; but unfortunately this is not always attainable. Many times, however carefully the inoculations are made, no effects are produced, the lymph being worthless. Now and then it contains septic matter, and very unpleasant local symptoms are produced.

The precise nature of the virus ought to be determined, if possible, and if it is a germ, pure cultures ought to be made, and the lymph prepared only from them. If it be a leucomaine, it ought to be freed from the presence of the dangerous ones. In fact, the production of lymph for purposes of inoculation ought to be in the hands of an elaborator, whose knowledge and skill are equal to the demands of the day.

In conclusion, I will say that if thoroughly treated, under the proper conditions, it will be found that vaccine lymph will do all that Koch's does, while the objections to its use cannot be so many nor so valid.

JOHN N. TAYLOR, M.D.

CRAWFORDSVILLE, IND.

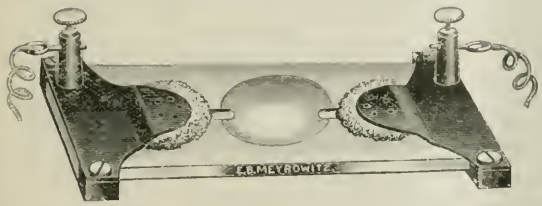
New Instruments.

ELECTRO-MICROSCOPIC SLIDE FOR TESTING THE ANTISEPTIC POWER OF ELECTRICITY.

BY R. L. WATKINS, M.D.,

NEW YORK.

I REPRESENT in the accompanying cut an instrument devised by myself for the purpose of ascertaining whether electricity would destroy the life of germs or not. It is



the result of a number of experiments to confirm the belief I have long held, that electricity is an antiseptic and disinfectant, and it was while I was engaged in these experiments that I discovered that Apostoli had made the same claim. The instrument consists of a glass slide, in the centre of which is a sunk cell. Two grooves, each three-fourths of an inch long, run from the sunk cell outward. Two brass pieces are fitted over the extremities of the slide in such wise that their rounded points, the under surfaces of which are lined with platinum, will cover a portion of the grooves. These rounded points should not touch the glass, but should be raised above the grooves about one-eighth of an inch. Binding posts are riveted to the brass for connection with a battery. In order to apply the instrument a sufficient quantity of the fluid containing the bacteria should be used to fill the sunk cell and grooves. A cover glass is placed over the sunk cell and its contents. Two small, clean sponges saturated with either the fluid or distilled water, are then placed underneath the platinum points and in contact with the fluid in the grooves. The bacteria are now ready for observation; the electricity is turned on and the quanitty required to stop all signs of germ life noted by the milliampère metre. They can now be cultivated on gelatine in the ordinary way, if desired, to determine whether their vitality has been entirely destroyed. Other uses for this slide will readily occur to one working in this field, *e.g.*, the effect of electricity on blood and different tissues. I have found this instrument very satisfactory, not only as an easy, but as a quick, way of finding out the amount of electricity required to destroy these micro-organisms.

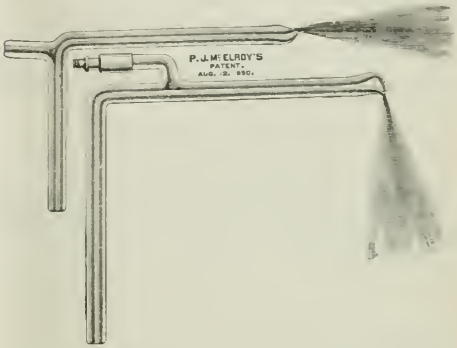
320 WEST 145TH STREET.

A NEW ASEPTIC ATOMIZING TUBE.

BY R. WETHERBEE, M.D.,

CAMBRIDGE, MASS.

SOME few months ago I was in the glass factory of P. J. McElroy, East Cambridge, Mass., and he gave me a set



of atomizing tubes for me to try in my practice which he had been experimenting on for a long time and at last had just succeeded in perfecting. All the tubes I have ever seen or used have their faults. The hard-rubber ones could not be used with all liquids; the glass ones with two tubes cemented or wired together were large and clumsy and all the time getting loose or separated.

This atomizer is a single glass tube with two holes through it. The bore of the liquid passage runs parallel with the air-passage and is drawn at the end to a point in such a manner that the liquid and the air come together as in an ordinary atomizing tube and forms a spray, either coarse or fine, and they can be made to throw the spray in any direction needed, the same as other glass tubes now in use. These tubes have a great advantage over all others, they are much stronger and can be kept perfectly clean. They are as small as any hard-rubber tube and being all made of annealed glass they can be boiled in water or immersed in any liquid without injury, thus making them perfectly aseptic. They can be obtained from Codman & Shurtleff, Boston, Mass.

Coffee-Drinkers in Europe.—According to a calculation published in the *Lancet*, but for the accuracy of which that journal will not vouch, the Dutchman drinks on an average 16½ pounds of coffee per year; the Belgian about half that quantity; the Norwegian about 6½ pounds; the German about 4½ pounds per head, being about two pounds more than the Frenchman, who has the reputation of being a great coffee-drinker; whereas, according to statistics lately taken, the Englishman consumes only half a pound a year, and the Russian one-fifth of a pound.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 23, 1891, to August 29, 1891.

PILCHER, JAMES E., Captain and Assistant Surgeon. Relieved from duty at Fort Clark, Tex., on expiration of leave of absence, and is assigned to duty at Fort Ringgold, Tex.

POLHEMUS, ADRIAN S., Captain and Assistant Surgeon. Leave of absence granted for one month, to commence on or about September 3, 1891.

WYETH, M. C., Captain and Assistant Surgeon. Sick leave of absence extended three months on surgeon's certificate of disability.

HAVARD, VALERY, Major and Surgeon. Granted three months' leave of absence, to take effect on or about September 5, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 29, 1891.

HESLER, F. A., Passed Assistant Surgeon. Detached from the Pensacola and ordered to the Charleston.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 29, 1891.

	Cases.	Deaths
Typhus fever	0	0
Typhoid fever	41	15
Scarlet fever	62	9
Cerebro-spinal meningitis	2	2
Measles	52	3
Diphtheria	73	22
Small-pox	0	0
Varicella	0	0
Pertussis	1	1
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

The Tetaniferous Man.—Verneuil applies this term to the individual who carries the virus of tetanus around on his person, although unaffected by the disease himself. The author discusses the causes and means of prevention of this affection from a clinical stand-point. If one considers the horse, with its secretions, excretions, and surroundings, as all capable of propagating tetanus, we cannot regard as impossible, infection by the secretions and excretions of man. The tetanic property of equine saliva has been demonstrated. The saliva of a human being may, for the time being, contain tetanus germs, and thus a bite from such an individual may cause tetanus. A case is given illustrating this. The secretions and excretions are only infected by the ingesta, so that the sperm, milk, and urine are never infected with the virus. He says: "I have already admitted, and now I admit more than ever, that a surgeon who has dressed a tetanoid patient may communicate the disease to other patients. I also admit that any person whatever, but above all a physician whose hands have been in contact with a horse, not tetanic, but simply tetaniferous, may infect the wounds of his fellow-beings, as in the cases cited. I also admit, finally, that such a man is not only dangerous to those whom he approaches, but may even give himself tetanus by auto-inoculation, either by wounding a part of the skin impregnated with the virus, as the plantar and palmar regions, or touching a wound on any part of his body with his impure hands." Two cases follow, in which he traces the cause to a wound inflicted on the skin, which was previously infected with the tetanic virus. The bacillus of Nicolaier was found in one of these cases. Three additional cases are given with a very careful analytical study of each.—*University Medical Magazine.*

The Medical Aspects of Marriage.—It is only right that medical men should have something to say upon the expediency of a marriage taking place between two persons in particular instances, but it is altogether doubtful whether, having pointed out the undesirable nature of a union upon physiological or pathological grounds, this advice would be adopted. There is no such thing as "future" with persons who have newly plighted their troth, they are too much absorbed in contemplating and revelling in the present. "The things that are" afford them all the satisfaction that they require without, in their opinion, demanding any consideration with regard to the things that might be. This state of affairs may be the natural outcome of those irresistible forces which are so egregiously prominent in the causation of marriages, but however this may be, the fact remains that the union of two persons is oftentimes inexpedient upon medical grounds. For example, no marriage should take place between persons having the same hereditary tendency to disease, a prohibition which is especially important in contemplated marriages between relatives. Again, it is perhaps very doubtful whether a hapless person, the subject of constitutional syphilis, should marry, or one with a well-marked tubercular taint, or one in whose family insanity is a distinguishing feature. Common experience, however, very fairly indicates that none of these conditions would be likely to interfere with the "understanding" arrived at by two persons who had determined to enter the sphere of matrimony, and medical men have, therefore, very little chance of pointing out deficiencies in such arrangements, even when these are palpable.—*Medical Press.*

Away with the Cigarette.—The *Annals of Hygiene* states that the Legislature of Michigan has recently passed a bill making it a misdemeanor, punishable by fine and imprisonment, to manufacture or sell, give or deliver, cigarettes of any kind of tobacco, or cigarette paper in books, or blocks for wrapping cigarettes.

AN ANALYSIS OF SEVEN HUNDRED AND FIFTY CASES OF RECTAL DISEASE IN PRIVATE PRACTICE

BY CHARLES B. KELSEY, M.D.,

NEW YORK.

THE following cases are taken almost exclusively from private practice, and the large majority of them from the upper walks of life. As a group they represent the diseases of people in comfortable circumstances, able to consult a specialist upon the first appearance of trouble. The relative frequence of the different affections may therefore be expected to differ somewhat from that observed in hospital or dispensary practice, among patients who have no time to be sick till compelled to seek help by suffering. They may be classified as follows:

Hæmorrhoids	262
Fistula	75
Fissure	52
Pruritus	51
Cancer	45
Non-malignant ulceration	40
Non-malignant stricture	39
Neuroses	32
Prolapsus	27
Abscess	22
Rectal and intestinal catarrh	18
Polypus	16
Constipation and atony	13
Impaction	7
Proctocele	6
Incontinence of fæces	5
Intestinal obstruction	5
Perityphlitis	4
Lacerated cervix	4
Esthiomène	4
Bleeding	3
Foreign bodies	3
Misplaced ovary	3
Invagination	2
Cystocele	2
Recto-vaginal fistula	2
Pelvic cellulitis	2
Pœderastia	2
Paralysis of rectum	1
Recto-vesical fistula	1
Purulent proctitis	1
Condylomata	1
	750

Comparing this table with Allingham's table of 4,000 cases from St. Mark's Hospital, which has so long stood as a standard, some remarkable differences appear at once. In that table piles compose only twenty-four per cent. of the total, while in mine they make up over thirty per cent. Again, in that table fistula composes nearly thirty-four per cent., while in mine it is only ten. This difference may be readily accounted for in two ways: First, by the fact that St. Mark's Hospital is a hospital "for fistula and other diseases of the rectum;" and, second, by the difference between public and private practice. Allingham himself says he has more piles than fistula in private practice, many of them being mild cases such as a patient in the lower walks of life would not consult a surgeon for.

Another marked difference in the relative proportions is seen in what I have grouped under the general head of neuroses. In my private practice these amount to about four per cent., while in Allingham's tables they are only 20 in 4,000.

Hæmorrhoids.—Considering now these cases more in detail, I find that of the cases of piles, fifty-two of the internal variety which were prolapsing and large enough to require operation were removed by the clamp and cautery. Concerning this operation I am very enthusiastic. Its rapidity and ease of performance, its perfect safety when properly done, and the freedom from pain which follows it, leave in my own mind little to be desired.

Regarding a single case of bleeding, showing itself as soon as the patient recovered from the ether, it is only necessary to say that it was from a cutaneous vessel cut in the groove made for the clamp, and not from the stump of the pile, and could have easily been controlled by a pad of lint and bandage had not the nurse lost her head and sent for another doctor near by, who preferred a ligature to a compress. Other hemorrhage than this I have never encountered, nor do I see how it can occur except by failure to thoroughly cauterize the cut surface held by the clamp. Of course, secondary hemorrhage may occur on the separation of the eschar, as it may with the ligature, but neither is to be feared.

Concerning the other operations for piles, making one hundred and three in all, there is nothing of interest. In fact, the only unsatisfactory case I have ever had in the treatment of this disease came from my use of carbolic acid injections, not included in this collection. Whitehead's operation I have never employed, and never shall till I am convinced that we do not possess in the clamp a much better one for the same class of severe cases.

Fistula.—Of the seventy-five cases of fistula, only the more unusual varieties possess any great interest. Of these there have been several, some of which had been operated upon several times before coming under my care. The interesting cases may, in fact, be distinctly divided into the following groups: 1, Those having an opening into the bowel, but none on the cutaneous surface; 2, those having multiple tracks, all of which have not been cut at a previous operation; 3, those the division of which involves loss of power in the sphincters, and hence incontinence.

The first group, generally known as blind internal fistulæ, has been chiefly interesting from a diagnostic point of view. I may say, in passing, that they are not at all uncommon, and are much more frequent now than before the popularity of injections as a cure for hæmorrhoids. The fluid injected into the hæmorrhoid not infrequently produces a slough along the course of the needle and beyond it. If this be large and involves the mucous membrane over its whole extent an ulcer is left, which usually heals kindly and results in a cure of the hæmorrhoid, at least for three or four years. But if the sloughing be limited to the track of the needle and the tissues immediately surrounding the fluid, it may involve the mucous membrane only at the point of puncture, and the patient is left with a blind, internal fistula—a much more painful and serious condition than that for which he was treated.

In one of my own patients I cut four of these fistulæ caused in this way by carbolic acid injections, and I have operated upon several coming from the practice of others. This complication was, in fact, one of the reasons leading me to abandon the use of injections, being simply an example of what is, I believe, a general law—that the amount

of inflammation which may be caused by introducing an irritant into a vascular tumor can neither be foretold nor limited.

In the diagnosis of these cases the one prominent symptom is pain—constant pain, but increased on defecation, and apt to be attended by numerous reflexes in the loins, genitals, and thighs. Physical examination reveals the opening of the fistula as shown by a point of ulceration, or the induration of the track leading away from the orifice. The treatment consists in laying the track completely open.

In the second class of cases, those of several tracks not all of which have been laid open, the diagnosis and treatment are equally simple. There has been much discussion as to whether some tracks will heal after others have been cut, but much the surest rule in practice is to divide them all. This is my invariable practice. I can imagine a fistulous track with which I should not care to interfere, but I have never seen one, though I have had some cases in which the disease was so extensive and the openings so numerous that all could not be divided at one time, for fear of the resulting constitutional depression. In such a case the injection of the tincture of iodine into the undivided tracks sometimes gives excellent results.

In the third class of cases, those in which a complete operation involves the danger of destruction of the sphincters, I have had an interesting experience, both in operating on the original disease, and in repairing the anus after incontinence has resulted from the operations of others. Of the six cases of incontinence included in this table four have been from operations for fistula, one from an old lacerated perineum, and one from the excision of a benign stricture. Of these the lacerated perineum and two of the fistulæ were completely cured by operation; the one resulting from the excision remains to be operated upon, and can easily be cured; one of the fistulous cases is now under treatment, and the last refuses operation, because, although he has no sphincteric power, he still has no trouble. In him the lower two inches of the rectum is converted into an open cicatricial tube easily admitting two fingers, and closed at the upper end by overlapping folds of mucous membrane. The function of defecation is, however, so naturally and regularly performed that he really has no need of a sphincter. At a certain hour every morning he feels warning of an approaching defecation, goes in the closet and relieves himself, and is through for twenty-four hours.

The case of lacerated perineum was an interesting one, the lady having been confined to the house for the incontinence for twelve years. After the birth of the child she was operated upon three times for the perineum, and superficially this was perfectly restored—only the fibres of the sphincter ani being unrepaired. She was a sufferer also from chronic intestinal catarrh with diarrhœa, and a certain amount of rectal prolapsus from lack of support to the parts. Visiting a celebrated physician for her chronic diarrhœa, she described to him the accident following the birth of her child, and without any examination he pronounced the condition incurable. This opinion from such a source seemed to her final, and for twelve years she wore a napkin and lived adjacent to a bath-room. It is hardly necessary to say that a few sutures restored the sufferer to the enjoyment of life.

In attempting to remedy the condition of the sphincter in these cases of incontinence following operations for fistulæ there are two guiding principles to be observed. The first is to try by a plastic operation to vivify and unite the parted edges of the divided sphincter, on exactly the same principle as in the operation for lacerated perineum. The second is only to be considered after the failure of the first, and consists in making an artificial stricture at the anus with the thermo cautery, without any particular regard to the true physiological action of the sphincter muscle. By one or the other of these operations almost all cases of fecal incontinence resulting from operations for fistula may be cured. The operator should, however, allow himself plenty of leeway in prognosis. Two or three attempts are often necessary to secure a final satisfactory result.

In all these cases of complicated fistulæ in which the division of all the tracks involves more than one division of the sphincters, the operation should be carefully considered before the patient is under ether, in order that the least possible injury to the parts consistent with a radical cure may be inflicted. As a rule, all fistulæ, no matter how complicated, may be laid open and made to communicate with a single incision through the sphincters. This presupposes ingenuity and skill on the part of the operator, but it may still generally be done, and a single incision of both sphincters (especially if posterior and median) does not generally lead to incontinence. I cannot in a report like this go into all the details of this operation, more especially as I have recently done so in this journal. But I may state the following rule: In operating on complicated fistulæ, make first a single incision through the sphincters, involving the main internal orifice. Then lay the secondary tracks open into this one, without again cutting the muscles, and as a rule no incontinence will result. One of the worst cases included in this table was that of a woman in the care of a general surgeon who, in dispensary practice, had had a large experience in this class of cases. Recognizing at once the danger of any ordinary operation for this particular case, he asked me to see it. The patient had had an abscess of the gland of Bartholini on each side, and each had opened into the rectum. Between the two rectal openings a cross-communication had formed with more than one secondary track. It was evident that division of the tracks meant a double complete division of the perineum, from the upper part of each labium majoram through the sphincter ani. A modified operation was done. A probe was introduced into each labial orifice, carried down to the anus, and brought out through the skin, so that the course should not implicate the sphincters. Through these tracks ligatures were passed and loosely tied as setons. The remainder of the tracks were then divided and made to communicate with a single incision through both sphincters, anteriorly. These last incisions healed promptly and cured all the tracks except the two in the perineum, in which the setons remained. These were left in until healthy reparative action had been set up, and then cut and withdrawn, with the result of a perfect cure and complete control; while by the ordinary operation a double division of the female perineum and of both sphincters, and hence an almost certain incontinence of fæces, could not have been avoided.

Abscess.—An examination of the table shows twenty-two cases of abscess, with sixteen operations. This includes only the cases independent of fistula—abscesses treated as such, some of them deep in the pelvis, and not those in which fistula had resulted before being seen.

Several of these cases have been very interesting. One of the early ones I only saw after it had caused the death of the patient from retention of urine. It was a large peri-rectal phlegmon which had been punctured on the surface a week before death, and was discharging freely. The man died in a convulsion with over-distended bladder and engorged kidneys.

Three were caused by injections of carbolic acid into hæmorrhoids. Of these two were slight, situated at the verge of the anus, and containing perhaps a drachm of pus each, while the third was a severe case of periproctitis with glandular enlargements in both groins, and swollen pelvic lymphatics. Fortunately the inflammation became circumscribed in the left side of the deep pelvis and a large quantity of pus and sloughing tissue could be evacuated through a free incision in the buttocks. The patient finally recovered. There were four other cases of deep pelvic abscess: one in a child of four years, breaking spontaneously into the rectum; one between the bladder and rectum, also discharging spontaneously

through the latter ; and one in the hollow of the sacrum which I cut through the buttock, after decided tenderness had shown itself in the right iliac fossa. All of these eventually recovered, though all were slow in healing.

In this list is also included one case of pelvic abscess in a woman, probably in the left broad ligament or tube. The diagnosis was confirmed by aspiration through the abdominal wall, and the pus was evacuated by an incision through the vagina.

Perityphlitis.—Three of the four cases of perityphlitis may properly be included among the abscesses, as in them the disease had gone on to the formation of a circumscribed collection of pus, which was safely evacuated by abdominal incision. In none of these was any accurate diagnosis as to the exact pathological condition at tempted, the abscess being simply opened through the abdominal wall and allowed to heal from the bottom. One of these healed kindly, a second required a subsequent opening through the rectum and drainage, but after this recovered; and a third never healed while under my care, but had one collection of pus after another, and one attack of acute general peritonitis, finally disappearing from my observation in a general hospital. The fourth case included under the head of perityphlitis was one of general suppurative peritonitis, from perforation either of the appendix or cæcum—which one not being accurately made out by the autopsy. It was a case seen by me in consultation, at a considerable distance from New York, and the patient was dying and beyond the help of laparotomy on my arrival. The autopsy was made by his physician, and perfectly established the diagnosis, but not the exact origin of the trouble.

Prolapse.—The twenty-seven cases of this class represent almost all degrees of the disease, from that of slight extent to masses the size of the fist which have come down and become strangulated. All of the thirteen operations performed have been either by linear cauterization alone, or by the method which I prefer, the clamp and cautery, used in very much the same way as in an ordinary case of extensive hæmorrhoids. Van Buren's operation of linear cauterization sometimes fails, but I have never known the clamp and cautery combined to do so.

Some of these cases, and pretty extensive ones, have been cured by the much simpler method of finding and removing the polypus upon which they depended.

Polypus.—The sixteen cases of polypus, with fourteen operations, include, I think, every variety of this affection, the hard and soft, single and disseminated, in children and in adults, except the insignificant form which is found associated with old hæmorrhoids and fissures, and which are snipped off at the time of the operation without much thought.

One has to learn by experience how severe a rectal catarrh may be caused by a very small warty growth. I have seen a little tumor, not larger when engorged with blood than the end of the index-finger, bring a patient nearly to the grave with suffering—diarrhœa, tenesmus, and hemorrhages ; and have seen the mucous membrane of the whole rectum softened, flabby, and bleeding on the slightest touch, from the irritation it had caused. When removed and collapsed, it seemed impossible so small a thing should have made so much trouble ; but there was no other disease, and the diagnosis was confirmed by the speedy restoration of the patient to health. Three or four such tumors, only smaller, may be found at the same time—so small that they have to be scraped off with the finger-nail or dull curette ; and when such a patient complains of severe rectal catarrh, these may always be regarded as a sufficient cause—at least such has been my own experience.

One of the most unusual cases I have ever seen was in a lady of middle age, suffering from a benign, but recurrent, papillomatous growth, springing from a section of the posterior rectal wall, the size of the palm. This whole area was covered with tumors, soft, friable, branching, breaking down easily under the finger, and each having its independent stem. Hemorrhage was never a marked symptom, but after removal with the curette they rapidly grew again, and when the patient imagined they had become so large as to obstruct the passage of fæces (which in reality they were too soft ever to do) they were again removed. Scraping, and the application of nitric acid never at all interfered with their rapid return, and about twice a year for several years they were removed with the dull curette. On each application of the instrument enough would be removed to fill a two ounce bottle. The patient died of an intercurrent affection, and though the rectum was sent me for examination, the growths had all been rubbed off by handling, and I could hardly distinguish by any changes the part of the rectal wall from which they had so frequently sprung.

Fissure.—Of the fifty-two cases of fissure, little need be said, except that about one-third of them were cured by simple applications of weak solution of nitrate of silver (grs. v. to x. to ℥ i.) on a camel's-hair brush. Where operations have been performed I have universally practised incision in preference to forced dilatation, and have never known it to fail to give perfect satisfaction.

Pruritus.—Of the fifty-one cases of pruritus, the majority have yielded to the ordinary line of treatment. Where an obstinate case is associated with hæmorrhoids, I have found the quickest way of overcoming the itching to be to operate upon the piles ; and in old cases, attended with infiltration of the skin of the anus and hypertrophied tags, I have become a firm believer in taking off the tags with the thermo-cautery as a radical means of reducing the infiltration and exciting a healthy reparative action. Where such treatment as this is not indicated, applications of nitrate of silver, one or two drachms to the ounce, have answered well.

Cancer.—Considering now the forty-five cases of cancerous disease, we find much of interest. In the first place the proportion of cases is much greater than in Allingham's table, which I take to show merely that in private practice more serious than slight cases seek consultations. In Allingham's collection there are only 105 cases to 4 000 in dispensary practice, while mine shows nearly half as many in 750. His probably presents much more accurately the relative frequency of the disease than mine. Of these 45 cases, 22 had advanced so far as to allow of no interference except colotomy, and this was declined ; in 5 colotomy was done ; in 4 a posterior linear division of the mass ; and in 3 extirpation. In 5 more an extirpation was possible, had the patient been willing ; but many of the sufferers come to me simply for confirmatory diagnosis, and with no idea of treatment. I have not been surprised in the past at the number of patients who have calmly submitted to the inevitable in this disease, because for some time I was not inclined to hold out to them any great hopes, either from colotomy or extirpation ; but as my own views on this subject have gradually changed, and as I now strongly recommend either one operation or the other in every case as soon as seen, I find I am operating on a larger percentage of the cases seen. I used to think colotomy offered little of comfort, but watching the agonizing course of a single case from its early diagnosis till its end in complete obstruction and rupture of the bowel, convinces me that anything was better than such passive helplessness. This particular case began in the prostate and only involved the rectum secondarily, so that it was never suitable for extirpation ; but there were many weeks when an artificial anus would have given untold relief of suffering. In this case also the operation could not long have prolonged life, for at the time of the fatal obstruction the disease had involved both the mesentery and the liver ; but even then it should have been done to relieve pain.

Proctotomy in malignant disease I have abandoned, because in the first place it can, in the nature of things, give only very temporary relief, and in the second, two out of four of my own cases have ended fatally as a result

of the operation. In both the patients were much exhausted by the disease, but I believe the shock of a rapidly performed inguinal colotomy would have been less.

Extirpation I still confine pretty much to the old limits —cases where the entire disease can be removed, and where I have no reason to suspect glandular involvement —in other words, to cases seen early, while the mass is still movable. The length of bowel involved is not a matter of so much importance, as opening the peritoneum seems to add but little to the risk of the operation, and by some modification of Kraske's incision almost the entire rectum can be reached.

I have also abandoned the old idea of postponing colotomy till signs of obstruction appear, for though I cannot prove that early operation delays the growth. I think it more than probable; and knowing that an artificial anus is not a thing to be dreaded in itself, it seems best to give the patient every possible advantage which may be gained by it. Moreover, it is impossible to tell how suddenly, and with how little warning, complete obstruction may set in. In one of my cases of stricture, not malignant, the patient (a physician, able to watch the course of his disease intelligently) and myself had many deliberate discussions as to just when I should make the artificial anus which we both knew to be inevitable. There seemed no hurry, though he was much constipated, and only relieved himself by purgation once a week. In the midst of our deliberations he purged himself once too often, and died in collapse from rupture of the weakened intestine. It was simply a valuable life sacrificed to the old and false dread of an artificial anus, for with an opening above the disease there was no reason why he might not have lived comfortably until he died of something else.

Another case, ending in the same way, taught me much. This patient was also a physician, and apparently in robust health; in fact, his magnificent physical development seemed to belie the possibility that the obscure symptoms he complained of could really portend a sudden death within a few weeks. The symptoms were soreness deep in the left iliac fossa, increased on defecation, and the occasional appearance of a little blood in the stools —nothing more. He had slight hæmorrhoids, but was sure the bleeding did not come from them; they were, however, removed, and after ten days he reported himself much better, then almost immediately after as bad as ever. A No. 7 rectal bougie passed easily the whole length (twelve inches), and showed no obstruction, and nothing but some fecal masses in the upper part of the sigmoid flexure could be felt through the pelvis. Dr. Janeway, who first saw the case, was guarded in his opinion, and gave no prognosis or diagnosis. For my part, though I told the patient a diagnosis was impossible except by exploratory laparotomy, I recommended no such measure, being much inclined to attribute the symptoms to intestinal catarrh of a simple form. He left New York for his home in the South, and in a few weeks we heard of his sudden death from obstruction, and on autopsy an annular cancerous stricture was found in the sigmoid flexure. Whether between the time of his leaving the city and his death any symptoms developed which would have made a diagnosis possible I do not know.

The case impressed upon me the great desirability of more accurate methods of diagnosis of stricture high up in the rectum. I believe they ought to be detected with the same accuracy as in stricture of the urethra, but I have not yet succeeded in accomplishing it, though still experimenting with bougies of various construction. I think this single case did more to teach me caution in diagnosis in disease beyond the reach of the finger than any I have ever met; though one other which came to me from the South with the same symptoms, only more marked, and with the diagnosis of cancer already made, in the expectation that I would do a colotomy, became entirely well a few months later by a simple milk diet. The six inches more or less of gut between the finger in the rectum and the fingers pressing into the pelvis, often make the physician feel his helplessness.

In the matter of diagnosis of cancer of the rectum, when the disease is within reach, the only thing that has ever troubled me has been to distinguish by touch between an old fibrous induration and a cancerous mass. Without the history of the disease to help, I do not know that even now I can always do it. The gut is blocked in either case by hard nodular masses of tissue, and the patients have much the same general appearance. But cancer has a peculiar stony, unyielding hardness that helps to diagnosis, and patients do not say the condition has existed for perhaps ten years. They are much more apt to say they were perfectly well till about six months before, when they first began to notice difficulty in defecation. I don't know that I have ever mistaken these two conditions, but I can imagine a case in which I should not be willing to commit myself without a microscopic examination and time to watch the development of the disease.

Intestino vesical Fistula.—In one of the cases of cancer of the rectum there was an opening into the bladder. The exact point of communication was not made out, but as the rectum was full of carcinoma, and the opening evidently low down in the intestine, it seemed but fair to presume that the communication was recto-vesical. The patient was in a miserable condition when placed in hospital, but rapidly improved after inguinal colotomy.

Non-malignant Stricture.—Of non-malignant strictures there are thirty-nine in this collection of cases, which I have grouped under the following heads: Venereal, 11; congenital, 1; traumatic, 4; tubercular, 2; dysenteric, 1; spasmodic, 1; arising from simple ulceration, 9; due to the pressure of the exudation in old pelvic cellulitis, 1; doubtful or undetermined, 9.

The point which first challenges attention in this arrangement is that in thirty-nine strictures which were non-malignant, only eleven can be definitely stated as venereal.

I really sympathized very heartily with a patient who came to me some months ago with a most interesting case of rectal disease. She had had stricture for years, and it had recently been excised, as near as I could learn, during an attack of complete intestinal obstruction caused by it, with an excellent result, except that there was complete fecal incontinence, which I proposed to remedy. In getting her history she, without questioning, gave me all the information which usually has to be gained by careful cross-examination, and ended with the remark: "Now I suppose, of course, you will say it is syphilitic, for every doctor I have ever had has said it must be, as long as it wasn't a cancer; and when I tell them I have never had syphilis they only look as though they thought I lied, but I never *have*." I have no doubt that she not only told the truth, but also was well able to judge of what she was talking about; and yet she very accurately expressed the prevailing idea in our profession, that strictures of the rectum not malignant are syphilitic, an idea which is often quite erroneous. It will be seen that even in the eleven grouped under this head I have intentionally used the word *venereal* instead of syphilitic, believing that, though secondary ulcerations and tertiary deposits do occasionally occur in the rectum and cause stricture, chancroidal ulceration and sodomy may do the same. In estimating the percentage of these cases, however, it would be well to bear in mind that these figures are taken entirely from the better class of society, and that of thirty-nine non-malignant strictures in dispensary practice a much greater proportion would probably be venereal.

This is not the place to discuss a question of pathology, but I cannot let slip an opportunity to beg for more careful clinical study of these cases by those who meet them in practice. If a few men would only study them a little more closely the profession would be the wiser, and we should soon know how many strictures of the rectum are due to chancre, how many to chancroid, how many to

secondary syphilitic ulceration in the rectal pouch, and how many to the later gummous deposit.

Passing this important question by with these few hints, we will go on to a more minute consideration of some of the cases.

I cannot say that I have ever seen a patient with cancerous stricture of the rectum get well, but I have certainly seen something very remarkable in this line.

The patient was a medical student in his second year of study, in perfect health till eight months before he came to me, at which time he began to pass blood, and supposed himself to be suffering from dysentery. This soon ceased, and three months later he discovered a growth in the rectum, three inches from the anus, which was sufficiently marked so that he had a piece of it cut out for microscopic examination, but on account of its poor preservation he received no report from the pathologist. He was next examined by Agnew, of Philadelphia, and pronounced to have cancer. Sands, of New York, concurred in this diagnosis about the same time. He then seems to have placed himself in the hands of both L. A. Stimson and myself. I declined to commit myself to cancer, and Stimson put him in hospital for examination under ether. At this examination I was invited to be present, and a distinct stricture was unmistakable, beginning at three and a half inches from the anus, and composed of small, nodular papillary growths. One of these was cut out and examined by Dr. Stimson, and in a verbal communication (I think I express his idea correctly) he said that, though he could not say the thing was then malignant, he had little doubt that it would soon become so.

Well, the young man, only twenty-two, was full of fight and determined to fight for his life. Having read in his text-books that arsenic might do good in malignant disease, he proceeded forthwith to poison himself with this drug. While I taught him how to use systematic dilatation, he took on his own responsibility immense doses of Fowler's solution, saturating himself with it again and again for over a year. This was in May, 1886. I examined him a few months ago, and he was practically well. There was no stricture, and only slight induration in the rectal wall at the site of the disease. I find in looking at the case in my book the word "cancerous" stricture has at some time been scratched out. Probably, were the diagnosis to be written again, it would be papillomatous growth in the rectum.

Four of these strictures have been of the anus, and not of the rectum, and have been caused by the removal of too much mucous membrane in the operation for piles. At least two longitudinal strips of membrane, half an inch in width, should be left on opposite points of the anus in every such operation. There is then no danger of undue contraction. All of these cases yield readily to gentle dilatation if it be properly employed. After the wounds have entirely healed, even if the anus be not large enough to admit the little finger, I begin by using a short, hard-rubber, straight stem, similar to what is used in the uterus, and of a size small enough to be introduced and left without causing the slightest pain. No matter if the size be no greater than that of a lead-pencil, after introducing it a few times on going to bed the patient will say he can bear a larger one, which may be substituted. In the course of a few weeks a bougie the size of the index finger can be worn for hours without pain, and the stricture will not recontract. The secret is to employ almost continuous dilatation, and never to try stretching. By continuous dilatation I mean putting in an instrument on going to sleep and finding it there on waking in the morning, without having been conscious of its presence. This, by the way, is the secret of all success obtained in treating strictures of the rectum by bougies. An instrument which causes pain by its introduction invariably does more harm than good, while one which can be introduced and retained without suffering almost invariably does good, if worn for sufficient length of time.

These strictures of the anus after any of the operations for piles are not uncommon, nor are they serious when properly handled in this way. The only mistake I have ever made in dealing with them was in the first one I ever saw, where I used too forcible dilatation, and for a time made the patient worse instead of better. The fact that the finest filiform bougie introduced through a urethral stricture and left in position for a few days may then be replaced by a good-sized sound applies as well to the rectum.

The single case of congenital stricture was one of great interest, having first called for treatment when the patient had reached the age of thirty-eight. He had always been constipated since childhood, and for a few years before being examined this had increased. On examination a sharp, falciform obstruction, not admitting the index-finger, was found in the rectum at about two and a half inches from the anus, without ulceration, infiltration, or any sign of pathological process. I thought at first a simple nicking of this band would open the canal, but in this I was mistaken. The constriction was not due to any redundant tissue which could be divided and leave the rectal wall as it should be, but was as if a string were tightly tied around the outside of this gut, constricting all its coats. In other words, to enlarge the canal it was necessary to do an internal proctotomy, cutting completely through all the coats of the bowels into the peri-rectal cellular tissue. As internal proctotomy without either division of the sphincters or drainage by a tube brought out by the coccyx is an operation which I consider so dangerous as to be almost unjustifiable, and as this patient did not care to undergo an operation like the latter, the stricture was simply nicked in three places and then treated by bougies. The result I cannot record, as he soon disappeared from sight, but the constriction seemed too firm to yield much to bougies. This causing increasing trouble as the patient reaches middle life is one of the diagnostic points of congenital stricture of the rectum, seemingly explained by the gradually increasing inelasticity of the tissues as the patient advances in years.

The one case of spasmodic stricture was very well marked, and at about the level of the internal sphincter, or perhaps slightly higher. It occurred in a physician having piles and slight ulceration, much worn by suffering from his rectal trouble. The first thing noticeable in the examination was the exquisite sensitiveness of the parts—a touch on the skin in the region of the anus causing him to cry out. For a long time the pain after defecation had been almost unbearable, and was increased by sitting down, and relieved by standing. The index-finger showed an impassable stricture or spasm at the point mentioned, and attempts to get above it caused intense suffering. The condition was verified by my partner, Dr. Gibbs, two days later, before ether was administered, and was seen to disappear as the ether was carried to the point of complete anæsthesia, though very slowly. The piles were removed, the ulcer incised, and the rectum thoroughly dilated. The spasmodic contraction has never returned.

Of the two cases of well-marked tubercular ulceration and stricture I lost one from diffuse periproctitis following an application of the actual cautery to the disease. A former application had produced an evident good effect upon the ulcer, and had led me to hope for an ultimate cure, but the second was disastrous. In the other case I did an inguinal colotomy with excellent effect, as far as relieving the symptoms which were rapidly carrying the patient to his grave. I have not examined the case for a year, and cannot say whether there has been any reparative action. But the patient is in much better general condition than before the operation, and very comfortable.

In the case of pelvic exudation the rectum was occluded in two places, one at three and a half inches from the anus, the other at the junction with the sigmoid flex-

ure. The latter was never discovered till the autopsy. This patient declined a colotomy, and had one attack of complete intestinal obstruction, which, however, she recovered from under the use of large doses of morphine and frequent tappings of the distended coils of intestine with a fine aspirator needle. The relief given by each of these means was very marked, but the morphine acted the more positively, the patient having several large, free, voluntary evacuations after being profoundly under the influence of the drug for forty-eight hours, with the respirations much diminished in frequency. As the constriction could have been in no way influenced by the drug, it seemed that its good effect could only be accounted for by stopping the violent and fruitless peristalsis which was visible through the distended abdominal wall. The patient died a few weeks later of heart and kidney complications.

Nine of these cases are put down as due to simple ulceration—that is, as neither tubercular, venereal, or dysenteric—and I have no doubt of the correctness of the diagnosis in any of these cases. Two were due to neglected hæmorrhoidal ulceration, and two, I think, could without much doubt be attributed to prolonged and difficult labors. The others seemed the result of old ulceration, the exact cause of which could not be determined.

As to the dysenteric stricture, I may also say that the history was very complete; and though much doubt has been thrown upon the existence of dysenteric stricture of the rectum, I have no doubt as to this case, nor do I believe the condition to be a very rare one.

Colotomy.—The forty-five cancers and the thirty-nine non-malignant strictures show three excisions, six colotomies, and seventeen linear proctotomies; but, as has already been intimated, another series of cases would show an increase in the number of colotomies, and probably also in the extirpations.

The colotomies have all been left inguinal, and I will say now that I have never yet accomplished anything but good by this operation, and never regretted its recommendation and performance, though I have had occasion to regret the opposite course. All of these cases are still alive, or were a few weeks ago, save one—all of the operations being within the last fourteen months.

The one case which died was operated upon on the patient's eightieth birthday. He was very feeble—nearly worn out with the disease—and the operation was merely a desperate attempt to prolong life and diminish suffering, undertaken with very grave doubts as to whether he would survive its performance. It was very rapidly performed, with the least possible shock, and the bowel was not opened till the expiration of forty-eight hours. Twelve hours after the opening he had two large fecal evacuations from the artificial channel, and then sank quietly and died, sixty-two hours after the operation. In this case I am not willing to admit that the operation shortened life, feeling that all that can be said of it is simply that it failed to accomplish what was rather hoped than expected of it.

I do not care in this place to enter into any discussion of the relative merits of the inguinal and lumbar operations, or to describe in detail what I may consider the best method of performing the one I always prefer—the left inguinal. It is enough to say that I can scarcely conceive any combination of symptoms of rectal disease that would lead me to prefer the lumbar to the inguinal incision, and that in my inguinal operations I have never been troubled either by disagreeable prolapsus or by the absence of a sufficient spur to prevent the passage of fæces past the artificial opening. In my operations I always secure a sharply defined spur by introducing a harelip pin under the bowel, and leaving it till adhesions have formed.

Proctotomy.—Of the seventeen operations of posterior linear proctotomy thirteen were in non-malignant strictures and four in cancers. Of the latter two were fatal, one a few hours after the operation, and the other within a few days, and a third was nearly so from secondary hemorrhage. In all of these four cases the disease was extensive, the operation long and difficult, and the shock correspondingly great—greater, I think, than would have been caused by colotomy. The procedure is, I think, much better adapted to non-malignant than malignant disease.

The operation in the thirteen simple strictures involved complete division of all the tissue below the stricture in some, posterior drainage by a tube brought out by the coccyx (after the suggestion of Weir) in others, and in only a single case was the incision confined to the stricture tissue, this one being followed by a severe periproctitis, from which the patient, however, recovered. The internal incision, involving as it does a free opening up of the cellular tissues of the pelvis, without any provision for drainage, can hardly be looked upon as justifiable according to our modern ideas of surgery.

As to the results of this operation, I should never regard it as a radical cure in itself for stricture, but combined with subsequent dilatation and local treatment of the accompanying ulceration it has in some cases proved remarkably satisfactory. I have cases under observation now in whom, though the stricture has never entirely disappeared, almost all of the symptoms caused by it before operation, such as pain, discharge, straining, and incontinence, have done so. I regard the complete division as only the first step in a long course of treatment; but one by which much time may be saved, and a much better result obtained in the end than by any other course. It is therefore my favorite procedure in cases of this class, not yet being convinced that with so good a means at hand the complete excision of non-malignant strictures is quite to be encouraged.

Acute Intestinal Obstruction.—Of these five cases, three have been perfectly simple in diagnosis and two doubtful. The first was a case of syphilitic stricture of the rectum, ending fatally from rupture of the bowel by active purgation. The second was due to stricture of the rectum and sigmoid flexure from occlusion by plastic exudation, and recovered under treatment by puncture and opium. The fifth was due to pressure of a cancerous growth springing from the promontory of the sacrum, and was complicated by acute peritonitis. The operation of inguinal colotomy was done, a large amount of serous fluid was evacuated at the time, and the patient made a good recovery. The fourth I was called to see in consultation in miserable quarters, at about midnight, and as there had been complete obstruction for nearly a fortnight, as the case was evidently one of tumor filling the whole pelvis and part of the abdomen, with pulse of 130, and no possibility of operating till proper antiseptic facilities could be provided, she was put upon medical treatment. The bowels moved freely under the influence of morphine after the consultation, and the patient survived about ten days. Diagnosis, cancer of the pelvis. The third and last was a medical rather than a surgical case, in which, after obstinate constipation for two weeks which yielded neither to the long tube or croton-oil, the patient made a rapid recovery under rest, morphine, and a pill of podophyllin. Diagnosis, fecal obstruction.

I must confess that these cases are about the most interesting I meet. I believe thoroughly in exploratory incisions for the sake of diagnosis, and am as ready to practise them as anybody; and yet it is only a few weeks since a case has occurred to me which is not included in this table, but which I will describe as illustrating the position in which one may be placed.

After a five-hour railroad ride I reached the patient at 11 P.M. He was eighty-six years of age, and forty-eight hours before my arrival had been taken down with the unmistakable symptoms of acute intestinal obstruction. Perfect health before the attack, except obstinate constipation for years and the history of one or two previous attacks similar to the present; sudden onset of symptoms after a meal; pain, swelling of abdomen, constipation,

fever, high pulse, vomiting—at first the contents of the stomach, later something described by one of the attending physicians as fecal and by the other as bilious. Twelve hours before my arrival he had become decidedly better. I examined the patient carefully. The abdomen was tense, hard, but painless. The patient was slightly delirious, and hiccoughing. The pulse and temperature had both come down to nearly normal; it was eleven at night, and there was no light to operate with. It was decided to use the long tube and wait till morning. Two quarts of water were introduced and evacuated, bringing away a small quantity of fæces, and two pills of aloes, belladonna, and strychnine were given. At 4 A.M. the patient was again examined. Hiccough had disappeared, pulse and temperature both lower. At 8 A.M. there was a considerable collection of fæces in the upper part of the rectum; the pulse and temperature were normal, the abdomen was less distended, and I decided not to operate. On the following day he had a natural fecal movement, and from that time on till his death, ten days from the onset of the attack, there were no symptoms. The bowels did not move again, but there were no signs of obstruction or of inflammation. No autopsy.

Invagination of the Rectum.—The two cases of intussusception included in the list were both invaginations of the upper part of the rectum into the lower, coming on at each attempt at defecation, and passing off spontaneously after a certain length of time. The condition is a peculiar one, and Cripps's description of a single case and the operation performed is the only one I have ever seen in print.

The symptoms are peculiar and almost diagnostic. The patient, if intelligent enough to express what he wishes to, will say that immediately on attempting to defecate the rectum seems to close upon itself, and that all straining only makes it worse. Also, that to get relief he either has to go many times and wait a long while, or else to assume some unnatural attitude. One of my patients could only relieve himself in the knee chest position. The condition may also be made out by a digital examination.

The operation consists in applying the cautery in three or four longitudinal stripes to the upper part of the rectum, to produce contraction. Paquelin's instrument should not be used, but one of the old-fashioned olive-pointed irons, heated to a dull red. If the iron be too hot, or too freely used, a fatal peritonitis may easily result.

The operations for proctocele, cystocele, and lacerated cervix need not be dwelt upon. They present nothing of interest, and were all undertaken in connection with operations for other diseases of the rectum.

Ulceration.—The forty cases of non-malignant ulceration without stricture would make an interesting study in themselves, as they include almost every variety of the disease, from the circumscribed red, eroded, and bleeding spot due to the pressure of impacted fæces, which heals when the bowel is unloaded; to the extensive cases of tubercular disease requiring colotomy. Distinct syphilitic ulceration of the rectal pouch without involvement of the anus, I have seen more than once, and have cured by combined local and general treatment. There have been four cases of lupus, or *esthiomène*, a word which, with R. W. Taylor, I believe should be dropped from our literature as expressing nothing definite. I have never had an opportunity, however, to treat one of these cases by destructive cauterization and *raclage*, as I should be glad to do; for there seems no reason why, when taken at an early stage, a healthy reparative action cannot be excited in this way. These patients all came from the lower walks of life, and I have never heard of the disease in any other.

The most frequent form of ulceration in my experience has been the hæmorrhoidal, resulting sometimes from mere neglect, and at others from some kind of ill advised attempt at cure. This form I have also seen result in well-marked stricture. Cases of slight ulceration from pressure of a misplaced uterus are also not uncommon; and more severe forms of the disease have been due to the injection of carbolic acid. Dysenteric ulceration is not so very rare in New York, and in some parts of New Jersey it is quite frequent.

The treatment of these cases requires more patience, tact, and therapeutic skill than any other class of affections of the rectum. Some of them can be seen at the first glance to be incurable by any means short of colotomy. In others, like the tubercular and lupoid, destructive cauterization and curetting with the sharp spoon may induce cicatrization; but in the tubercular variety I think this only applies to those in which the process is comparatively limited. In the cases of dysentery, voluminous injections of nitrate of silver, one or two grains to the ounce, have sometimes acted surprisingly well. The less serious forms, ulcers of limited area within the reach of local applications, may be successfully treated by nitrate of silver, acids, division with the knife, and astringents.

Neuroses. — The thirty-two cases grouped arbitrarily under this head represent many phases of disease. The term, nervous rectum, though far from being a diagnosis, represents a very distinct affection to the practitioner. It can only be applied to the patient who, without any discoverable lesion, still complains of being conscious, and often very disagreeably conscious, of the existence of his rectum. Almost any lesion of this part may cause unusual and annoying reflexes, such as pain in the loins and legs, disturbances of the genito-urinary organs, irritation of other parts of the alimentary canal, as shown by indigestion and loss of appetite; and, indeed, may manifest itself by an irritation at almost any point in either the cerebro spinal or sympathetic nervous system. Some of these cases have been very curious. I have had two patients in whom the act of defecation and the protrusion of a mass of hæmorrhoids has caused at each act a decided faintness, and this neither from pain or loss of blood. One of these was an athlete with comparatively little trouble. A physician told me not long ago that he was so nauseated after everything he ate that he had ceased to try to take any solid food. He had a bad pruritus with small hæmorrhoids, and the morning after the operation he ate a hearty breakfast for the first time in months. Pain in the foot is a very common symptom of rectal disease, but trouble in locomotion, strongly resembling incipient locomotor-ataxia, I have never seen but once. This was in a case seen with Dr. Spitzka, and curing the rectal trouble put an end to all the symptoms.

It is manifestly impossible to promise a cure of these reflexes by an operation, but the physician who did so would be more often right than wrong, and it is, at all events, not a bad plan to be on the watch for rectal trouble in patients presenting such anomalous troubles. I operated some months ago on a stricture of the rectum, and secured a very happy relief from abdominal pain, in a case in which two of my gynecological friends had recommended removal of the ovaries. The patient tells me neither of them examined her rectum or discovered that she had any trouble there.

These cases, however, are all entered under their proper headings, and the thirty two cases here referred to are cases in which no disease could be discovered. Some of them were cases of simple neuralgia; in many the patients could hardly describe in words the nature of their discomfort. For example: an intelligent young physician consults me because, when sitting for any length of time, he feels a sense of heat, almost amounting to burning, in the rectum. This is not fancy, for it keeps him walking around in his office and prevents his enjoying the theatre or opera. Another patient complains that she has pains on sitting, so that she always has to sit on the edge of her chair; and for some months past she has had from three to six watery passages on waking in the morning, as though

she had taken a large dose of salts. There is no sign of ulceration and no coccygodynia, in fact no disease of any sort discoverable. Another complains of acute pain after stool, extending into the groin, affecting the neck of the bladder, and causing vomiting and great prostration. Such attacks come once in six months, last a day or two, and the patient is perfectly well in the intervals. Examination absolutely negative! These are simply examples of a large class. But the condition may be more serious than this, and a patient may become so firmly convinced that he has serious disease with his rectum as to become hypochondriacal upon this as upon any other point. Of course, the treatment of such cases must be on general principles. I have discovered, however, that to insist upon etherization and dilatation of the sphincter for a thorough examination, if it does not effect a cure, generally suffices to effect a change in the medical attendant.

ON THE EFFECTS OF CERTAIN DRUGS ON THE VELOCITY OF THE BLOOD-CURRENT.[1]

By JOHN C. HEMMETER, M.D., PHIL.D.,
BALTIMORE, MD.

The velocity of the blood-current in an artery is determined by the ratio of the quantity of blood that flows through it in a given time to the sectional area. In other words, the figures representing the volume of blood that passes through an artery in a given time, say in one second, divided by the figures designating the sectional area of that artery, will give as the quotient the mean velocities of the current in the various areas of the arterial system. As these sectional areas differ in various vessels, and in various parts of the same vessel, so must the velocity differ. The velocities are in fact inversely proportional to the sectional area.

As the total sectional area of the arterial system continually increases from the heart toward the periphery, the velocity of the current naturally decreases from the heart toward the periphery.

The velocity and the tension of the blood current at beginning of the arterial system is dependent upon two factors: 1, The energy of the activity of the heart; 2, and the sum total of the resistances of the vascular paths. Both of these factors—the energy of the heart activity and the sum of peripheral resistances—are variable.

The heart's action continually varies in the normal animal in the rate of its rhythm, the force of contraction, the tonicity, and probably conduction, and the sum of the peripheral resistances varies mainly through vaso-motor influences exerted upon the small arteries. To gain a better conception of the influences that govern the rate of the current it is most expedient to consider the possible variations to which these two main factors of heart activity and peripheral resistance are subject.

I. The energy of the heart contractions remains the same and the resistance (*a*) increases, then blood-pressure increases and velocity decreases. (*b*) Resistance decreases, then blood pressure decreases and the velocity increases.

II. The energy of the heart activity increases and (*a*) the resistances are the same, the blood-pressure and velocity increase. (*b*) The resistances increase, then blood-pressure increases and velocity remains the same. (*c*) The resistances diminish, then blood-pressure remains the same and velocity increases.

III. The energy of the heart activity decreases and at the same time (*a*) the resistances are the same, then blood pressure and velocity are reduced. (*b*) The resistances are correspondingly greater, then blood-pressure remains the same and velocity decreases. (*c*) The resistances are correspondingly smaller, then blood-pressure sinks and velocity is the same.

[1] Experiments made in the Biological Laboratory of the Johns Hopkins University.

There is no constant relation between the sizes and volumes of the various branches that develop from the aorta. Experience has shown that variations of resistance occur in circumscribed areas of the peripheral arterial system, while heart-action and blood-pressure remain unaltered. This is possible only if the restriction of the discharge, *i.e.*, the diminution of the current volume in one branch, is counterbalanced by compensatory increase in the current volume in other branches; therefore the velocity in different arteries varies at the same time in an alternating equalizing manner; from this it follows that in investigations of the velocity of the current in one and the same vessel one finds great variations in the velocity in consecutive periods of time which bear no constant relation at all to frequency of the pulse or to blood-pressure.

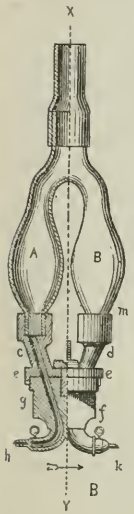
To form an approximately correct idea of the rate of the current in any artery one cannot judge from one measurement taken in one single period of time, nor even from two or three such measurements. From experience one learns that the mean of the results of at least six measurements must be calculated, taken in six consecutive periods of time. In the experiments to be detailed the results are based upon the average of six measurements taken once every two minutes. There are, of course, measurements taken oftener than once in two minutes, but they are for brevity's sake excluded, and only the measurement at the end of every second minute taken, during twelve consecutive minutes, to make up the average.

We have studied the effect of ergot, digitalis, and alcohol on the rate of the blood-current in the carotid artery. The animals used were dogs and cats. The drugs were allowed to run into the jugular vein, diluted with defibrinated blood from another animal of the same kind. For this purpose, and also to be able accurately to determine the amount which entered the circulation, a cannula in the jugular vein was connected with a eudiometer. In case of ergot we employed a solution of the officinal fluid extract, 1 c.c. to 9 c.c. of defibrinated blood, and also a solution of ergotole (S. & D.), 1 c.c. to 29 c.c. of defibrinated blood. In case of digitalis a ten per cent. solution of the tincture and a twenty-five per cent. solution of the infusion, in defibrinated blood, were made use of. A solution of digitalin was also experimented with, in form of a solution in defibrinated blood, .005 gm. digitalin to 100 c.c. blood. In case of alcohol, solutions of varying strengths of Squibb's absolute ethylic alcohol in defibrinated blood were used. Defibrinated blood injected into the jugular vein as such had no appreciable effect on the rate of the current in the carotid, as far as could be determined by the instrument which was used for that purpose, and which will presently be described. The drugs were in every case mixed with 50 c.c. of normal salt solution, and this again added to 50 c.c. of defibrinated blood.

A number of instruments have been devised to measure the velocity of the arterial current—Volkmann's hæmodromometer, Vierordt's hæmotachometer, Chauveau's hæmodrometer, and the hæmodromographs of Lortet and Marey—all have been shown to possess objections. The best instrument which has thus far been invented for this purpose is the so-called stromuhr of Ludwig (stromuhr, current-clock); even this instrument has not entirely surmounted the difficulties, still it is the most accurate we have.

The stromuhr consists of two ovoidal glass cylinders or globes, the capacity of which is accurately known and is equal in both. These two globes are continued upward in a tubular manner, and connect with each other by a U-shaped curvature. On the convex side of this curve there is a short exit tube which can be hermetically closed. The lower ends of the globes are held in two metal tubes (*m*, *m*), the other ends of which communicate with two cannulæ, *h* and *k*, that are inserted in the ends of a divided artery. The course of these tubes is

at one place interrupted by two metallic disks, which are accurately fitted upon each other. The two upper ends of the tubes coming from the ovoidal globes are fitted into the upper disk so that its perforation exactly strikes the lumen of the lower tubes in the lower disk. The part of the instrument resting upon the upper disk can be rotated in a circle of 180°. By this rotation the globes of the current-clock can be alternately brought into communication with the two cannulæ.



In the experiment the globe nearest the cardiac end of the artery is filled with pure olive-oil (this oil should be previously shaken with distilled water to free it from all oleic acid and mucin), while the globe nearest the distal end is filled with defibrinated blood. The globes each will hold 5 c.c. When a measurement is taken the blood enters from the artery into the first globe, displacing the oil, which is pushed over into the second globe, while the defibrinated blood is forced into the peripheral part of the artery.

As soon as all of the oil is forced from globe A to B, by the inrushing blood, the stromuhr is turned through 180°, by which the oil is again placed nearest to the cardiac end of the artery. In every new rotation after this the oil is displaced by blood, the blood in the second globe by oil, the main point of observation being to note the exact time it takes for the blood to displace 5 c.c. of oil. The velocity is measured by the ratio of the quantity to the sectional area.

Suppose the sectional area of a dog's carotid to be $3\frac{1}{8}$ mm., and the oil had been displaced ten times in 100 seconds, the space occupied ten times by the blood in replacing the oil being 10×5; hence 50 c.c. of blood have been delivered in 100 seconds, then $\frac{50.00 \text{ quantity}}{3.2 \text{ sect. area}} = 156$ mm. of blood per second, the velocity.

The following are tables giving the results of one of the experiments each, that were made with ethylic alcohol, digitalis, and ergot:

Experiment No. 1, with Ethylic Alcohol, Ten per cent. Solution—Diameter of Carotid Cannula, 1.61 Mm.

A. NORMALLY.

Volume of Stream in 1 Second in Cubic Centimetres.	Mean Velocity in 1 Second in Mm.
0.33	190
0.25	142
0.28	142
0.33	190
0.23	143
0.19	140

Average of six measurements under normal conditions ..... 158.0 mm.

B. UNDER ETHYLIC ALCOHOL.

1.6	338
1.3	339
2.0	410
2.3	432
2.5	460
2.0	416

Average of six measurements under ethylic alcohol ..... 399.1 mm

Increase of rate of current under alcohol 241.1

Experiment No. 2, with Digitalis—Diameter of Carotid Canula, 1.61 Mm.

A. UNDER NORMAL CONDITIONS.

Volume of Stream in 1 Second in Cubic Centimetres.	Mean Velocity in 1 Second in Mm.
0.33	188
0.22	125
0.28	161
0.33	188
0.25	141
0.33	188

Average of six measurements under normal conditions ..... 165.16 mm.

B. UNDER DIGITALIS.

0.20	120
0.14	84
0.10	72
0.20	120
0.20	116
0.12	80

Average of six measurements under digitalis ..... 98.60 mm.

Difference between rate of current normally and under digitalis 66.56

Experiment No. 3, with Ergot—Diameter of Carotid Cannula, 1.61 Mm.

A. UNDER NORMAL CONDITIONS.

Volume of Stream in 1 Second in Cubic Centimetres.	Mean Velocity in 1 Second in Mm.
2.0	340
1.7	312
1.69	314
0.72	392
0.72	390
1.7	318

Average of six measurements under normal conditions ..... 344.3 mm.

B. UNDER ERGOT.

1.0	198
1.7	206
1.3	210
0.6	204
0.6	114
1.6	200

Average of six measurements under ergot ..... 188.6 mm.

Difference between rate of flow under normal conditions and under ergot. 155.7

In the experiment we have recorded concerning ergot it is clear that the rate of the flow was diminished by 155.7 mm. Under digitalis the stromuhr showed a reduction of the rate of the current of 66.56 mm. Under ethylic alcohol, however, the rate of the current was increased by 241 mm. per second. These main conclusions are supported by the remaining experiments (four with each drug) and the figures are based upon the averages of six measurements.

A number of experiments have been rejected because in one way or other they were failures. It will probably be a safe method to use the stromuhr in the current of the femoral instead of the carotid artery, because of the easier manipulation of the instrument in this region; in the neck, the trachea, jugular vein, and vagus add to complicate the operation.

The result of every experiment showing, with very slight variations, that ergot and digitalis reduce the rate of the current while alcohol increases it, the question

raises, "Are there any facts known concerning the physiological action of these drugs which could explain these observations?"

It is established beyond a doubt that ergot diminishes the frequency and force of the systolic contractions and that it constricts the arterioles. For the literature bearing on this we will refer to the writer's recent contributions to the subject (J. C. Hemmeter, "An Experimental and Clinical Study of Ergot," *Medical News*, January 31, February 7, March 7, and March 14, 1891). As ergot, therefore, diminishes the energy of the heart activity, and at the same time increases peripheral resistance, its effects must be classified under heading No. III., section *b*, on page 292 these influences being sufficient to explain the power of ergot to reduce the velocity of the blood-current.

Concerning digitalis it may be stated that it has been determined by many observers that this drug (1) decreases the work of the normal heart (see Jörg, *Archives de Médecine*, 1er. sér., i. xxvii., p. 107; also Saunders, "On Foxglove;" Hutchinson, quoted by Homolle and Quevenne, *Arch. de Physiol. de Thérap.*, etc., No. 1, 1854; and H. H. Donaldson and Mactier Warfield, "Studies for the Biol. Laboratory," Johns Hopkins Univ., vol. ii., p. 335). (2) That it produces contraction of the arterioles (see Fothergill-Schmidt's *Jahrb.*, vol., cliv., 1872; also *British Medical Journal*, July and August, 1871; Gourvat, *Gazette Médicale de Paris*, 1871; Briesemann-Schmidt's *Jahrbücher*, vol. cliii., p. 29; Boldt, Inaug. Dissert., Schmidt's *Jahrbücher*, March, 1872; Ackermann, *Deutsch. Archiv f. klin. Med.*, vol. xi., p. 125; Donaldson and Stevens, *Medical News*, Phila., xli., p. 697).

For fuller references to literature on the effects of digitalis in reducing the work of the heart, and in constricting the arterioles and capillaries, we would direct attention to the work of Donaldson and Warfield, and Donaldson and Stevens, above quoted, also to the works on therapeutics of H. C. Wood, Lauder Brunton, Ringer, Köhler, and Binz.

The physiological actions of ergot and digitalis in reducing the rate of the blood-current are very closely allied, and might be arranged in the same category before stated, namely, No. III., section *b*.

The cause of the increase of the rate of the blood-current observed under alcohol will have to be exclusively sought in its property to cause dilatation of the arterioles and capillaries, thus diminishing peripheral resistance to the blood-stream, for Professor H. N. Martin has shown that there is no increase in the rate of the heart-beat, and therefore, probably, no increase in the work done by the heart in the normal animal (H. Newell Martin and L. T. Stevens, "Studies for the Biological Laboratory," vol. ii., p. 477). Professor Martin has also shown that the work of the isolated mammalian heart is actually diminished under alcohol, the character of the heart-beat being so altered through swelling of the myocardium that the ventricular cavity is not obliterated at the end of the systole. These observations have been confirmed by the author. It must be remembered in the clinical application of alcohol that the action of this substance is different in the organism that is pathologically altered from what it is in the normal one. Thus it is most probable that in fevers and acute inflammatory diseases the pulse-rate is reduced by alcohol. It was formerly held by some investigators that this reduction of the pulse-rate in fevers, etc., under the use of wine, whiskey, etc., was possibly the effect of some of the other constituents of these liquids, not to the alcohol contained in them. The author, however, has convinced himself, in a case of typhoid fever, and also in one of pulmonary tuberculosis, that 20 c.c. of absolute alcohol in 80 c.c. of water, will, within twenty minutes, reduce the rate of the pulse, in case of the enteric fever, from 112 to 96, this reduction was noticed three times in the same case of typhoid fever. Under the same dose a fall from 128 to 98 was noted in this patient on another occasion.

However, the opinions concerning the action of alcohol in the work done by the heart may vary concerning pathological conditions. The most reliable observations, those already quoted, seem to point conclusively to the fact that the work of the normal heart is not increased at any rate; if, therefore, the velocity of the blood-current is increased under alcohol, this can be due only to its diminishing peripheral resistance to the blood-stream by dilating arterioles and capillaries; that alcohol has this effect was shown by Parkes, Bouvier, Marvaud, Zimmermann, Richardson, and the author. For fuller references on the literature of this subject we would refer to the work of Professor H. N. Martin, already quoted, and that of the author (J. C. Hemmeter, "Recent Experiments on the Physiological Action of Ethylic Alcohol," "Transactions of the Medical and Chirurgical Faculty of Medicine," 1889, p. 229; also, J. C. Hemmeter, "On the Comparative Physiological Effects of Certain Members of the Ethylic Alcohol Series on the Isolated Mammalian Heart," "Studies from the Biological Laboratory, Johns Hopkins University," vol. iv., No. 5).

The therapeutic significance, if any, of the results obtained we are not prepared to discuss, but we may point out that experiment confirms clinical experience, in case of ergot and digitalis, as applied to hemorrhage, for if the quantity of blood that flows through an artery in a given time is reduced by these agents, their application to processes of transudation and hemorrhage becomes rational. And again the dilatation of the blood-vessels and the increased velocity of the blood-current under alcohol may explain in part many of its clinical applications, for every physician knows how effectively the freer and fuller current of blood through the nobler organs acts as a resuscitating stimulus in many diseases.

THE NATURAL COURSE OF CATARACT.[1]

By H. H. SEABROOK, M.D.,

SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

Two facts forcibly strike the student of ophthalmological literature. First, the enormous number of kinds of medical treatment that have been used for the improvement and cure of cataract; and, second, the absolute and unqualified success of each method, if we are to believe the statements of the men originating or reviving it. A critical examination of the records reveals a curious and significant state of affairs. Homœopathy stands far and away ahead of any other system in its claims as to the number and efficacy of cataract cures.

In the *Journal of Ophthalmology, Otology, and Laryngology* of 1889 the treatment advised by one man alone, who claims to have cured three cases, consists of appropriate homœopathic treatment internally (let us thank the author for sparing us the details), and locally hot fomentations, galvanism, chloral, cantharis, or mustard, with occasional dry cupping. Since 1861, when von Jaeger was accused of having believed in some cure which he preferred to keep secret, no ophthalmologist of national or international fame has claimed to cure uncomplicated senile cataract by treatment other than removal of the lens except Sperino.

Life is too short for the enumeration of all the internal remedies that have been used by regular physicians to cure cataract. Some of the principal were: Mercurials—Boerhaave, 1750; Janin, 1788. Setons, alteratives, and purges—Curtis and Warnatz, 1835; Larray, 1836. Strychnine—Schneider. Carlsbad water is said to have cured one case in one dose, Arlt, 1833. Alteratives and purges followed by tonics—Moyne (Naples), 1882 (*Bollet d'oculista*). Combined local and general treatment have made, perhaps, more of a sensation for the time being. Electricity was first recommended by Hinley, in 1843, but he used internal remedies and waited for nature as

[1] Read before the Ophthalmological Section of the New York Academy of Medicine, May 18, 1891.

well. In two cases Arlt claimed, in 1833, to have effected a cure by the use of a salve locally, with Carlsbad water internally. Phosphorus, locally and internally, made a tremendous sensation after the claims of Tavignot, in 1868.

The local treatment of cataract has always been the most popular. As might have been expected, massage was the first local treatment to be used. Costomiris (*Arch. d'Ophthal.*, No. X.) says that massage was used for cataract by the ancient Greeks. He distinguishes nine kinds of massage, according to the amount of pressure used and the duration. Hippocrates distinguished four kinds. As a rule, since that massage has been combined with some salve, as in Arlt's cases in 1833, or solution, and the supposed virtue of the treatment ascribed in part or wholly to the medicines.

Electricity, as above mentioned, was first used in 1843 for curing cataract, and has been used at irregular intervals for this purpose since. Colburn (*Journal of the American Medical Association*, 1887) makes a very fair showing in his cases of equatorial cataract treated by electricity, if it should be acknowledged that this form of cataract is necessarily progressive.

Of all local treatments that of Sperino deserves the most respect. He revived the old method of Hecquet, 1729, and De Villards, 1740, repeated tapping of the anterior chamber, and in 1860 reported success in forty cases. This treatment was founded on a well recognized change in the composition of the aqueous in certain cataracts, and was supported by many ophthalmologists of the time. But Borelli, Torresini, and Rivaud-Laudrau successfully attacked the method by showing such bad results that Becker says it entirely disappeared. However, Bänziger, Zurich, 1889, reported a case of cataract in a child in which he unsuccessfully performed discission, the capsule closing rapidly after each operation. One month later the cataract in one eye was found to be absorbed. Bänziger ascribes the absorption to the repeated tapping of the anterior chamber.

At the time of the meeting of the first International Ophthalmological Congress, in 1857, cataract cures were rife, and cases cured by ammonia to the temples, and another by iodide of potassium were reported. A committee was appointed to consider the question and reported through its chairman, M. Testelin, as follows: "There does not exist, in the annals of science, one authentic proof that a cataract has retrograded or been arrested in its course under the influence of any medical treatment whatever."

Authentic cases of absorption of cataract spontaneously have been reported from time immemorial. In answer to De Wecker's claim that such a thing had never happened, Meyer collected a number of cases, which are published in v. Graefe's *Archiv*, No. 33. For full details of the earlier cases I would refer you to his article. Cases of the spontaneous absorption of traumatic cataract are of common occurrence and need not be enumerated. Doubtful cases, such as Albers's in 1804, Hinterberger's and Estlin's in 1829, need not be detailed. The only pre-ophthalmoscopic spontaneous cure that appears to be reliable is that reported by Warnatz, in 1835, of bilateral cataract which had been brought on by a hunger-cure for rheumatism. E. von Jaeger, in 1861, reported many cases of improvement and two of cure of "cloudy interlamellar substance," one in a man aged twenty-five, under observation four years, the other a woman, aged forty-two, under observation twelve years.

Holscher (*Walther and Amman's Journal*, vol. xxxii.) reports two cases of congenital cataract in children completely absorbed in fifteen years. The father of these children had cataract.

Gorecki, in 1875 (*Recueil d'Ophth.*), reports the correction of a myopia by the spontaneous absorption of a cataractous lens where posterior synechia was present.

Becker, in *Graefe and Saemische*, reports the absorption of an equatorial cataract in a woman sixty years of age.

Tamanscheff, 1878 (*Gazette des Hôpitaux*), claims absorption in a case of cataract.

Schiess, in 1882 (*Correspondenzblatt f. Schweitzer Aertze*), reports the absorption, in four months, of a cataractous lens in a twenty-five year old patient.

Armaignac (*Journal de Médecine de Bordeaux*, No. 25) reports a case of rapid formation of cataract in a case of irido-choroiditis and rapid clearing of the lens substance afterward.

Szili, in 1884 (*Centralblatt f. prakt. Augenheilkunde*), gives full details of a case of absorption from spontaneous rupture of the capsule in a sixty-five year old patient.

Lange, in 1884 (*Arch. f. Ophth.*), reports the absorption of the upper portion of a lens with Morgagnian cataract, and gave further details the next year—V. $\frac{4}{LX}$ with sph. + D. 9.

Nordman, in 1885 (*Arch. f. Augenheilk.*), reports a similar case—V. $\frac{1}{6}$ with + D. 11; when combined with the stenopaic slit $\frac{6}{IX}$ —.

De Wecker now got in out of the cold by reporting two such cases (*Traité Complet d'Ophth.*).

Nettleship, in 1885, reported three cases of spontaneous cure of diabetic cataract—two of Regen's, one of Tannahill's (*British Medical Journal*).

Bretthauer, in 1886, reported three cases of spontaneous absorption within the capsule. One had before been reported by him before with V. of $\frac{20}{LX}$ — with sph. + $\frac{1}{6}$.

Berlin and Leber have each reported a case of cure following iritis, and a similar case was reported to the Société Médicale at Berne by Dor.

Kipp, in 1887, reported a case of spontaneous cure of cataract—V. $\frac{18}{XXX}$ (*American Journal of Ophthalmology*).

Nicati, in 1888, reported a case of Grange's, in which the upper part of the lens in a case of Morgagnian cataract was absorbed—V. $\frac{1}{6}$. The fluid in the upper part of the capsule was later absorbed, leaving the nucleus and capsule. Nicati also reported a case of his own of spontaneous absorption in a patient seventy-eight years of age. Vision perfect; a myopia of D. 9 had disappeared (*La France Médicale*).

Ocana, of Madrid, reported another case of absorption the same year.

Desogus, in 1889, reported a similar case (*Riforma Medica*).

Baker, in 1889, reported improvement in a diabetic case from a V. of fingers at 6 inches to $\frac{20}{LXX}$ O. D., and $\frac{20}{LX}$ O. S. In a nephritic case from $\frac{20}{CC}$ to $\frac{20}{L}$, and another of absorption of an equatorial cataract five years after Agnew had diagnosed it and corrected the regular astigmatism (*Cleveland Medical Gazette*).

Risley, in 1889, described four cases of cataract from choroiditis with great improvement of vision, which he ascribes to the cure of the choroiditis, merely claiming that the lens process became stationary (*University Medical Magazine*).

All the foregoing cases do not throw much light upon the natural course of cataract in general. The only attempt that I know to have been made to obtain statistics of the natural proportion of improving stationary and progressing cataracts so far was made by Brailey, who reported a number of cases to the Ophthalmological Society of the United Kingdom, December 11, 1890. According to a review of this paper in one of the French journals forty-five per cent. of Brailey's cases remained stationary, thirty-three per cent. retrograded. Four cases improved and four matured. The stationary cases were all cortical.

In order to illustrate some well-known facts concerning cataract, which are unfortunately often overlooked because they have never been popularized, I have collected and carefully tabulated 87 cases of cataract occurring in 57 patients. For the records of four cataracts I am indebted to Dr. H. D. Noyes. Five were private cases of my own, the histories not having been written recently. The remaining 78 (in 52 patients) are from the records of the clinic of Dr. C. S. Bull, at the New York Eye and Ear Infirmary, and include all cases tested two or more times, with an interval of over a week between the tests, from 1876 to 1891.

Dr. Noyes's cases as well as my own have a larger proportion showing improvement in V. than Dr. Bull's, not having been so long under observation. All cases with V. less than $\frac{5}{CC}$ have been rejected, as being nearly mature and not probably as reliable as the others, although the record showed improvement of V. in a goodly proportion of even these. All cases in which diabetes or Bright's disease was noted are not reported, as well as cases of secondary cataract. These cases were examined and recorded with no object in view, such as showing improvement of V. In fact such improvement was usually questioned, and failure of V. was looked for and in the cases not incipient desired. As a proof of this, several cases where Förster's operation for ripening the cataract was done are among the number. While it is freely acknowedged that some of the tests were not absolutely accurate, it is claimed that they are fully as reliable as any ordinary dispensary tests, to say the least. That in general the variable V. is due to the nature of the pathological process is certain, for no other class of chronic cases in these records show any such variability except those with vitreous opacities. In 41 of these cataracts occurring in 29 patients, there were two tests recorded, the shortest time between them being ten days, the longest six years, the average five and a half months. Twenty-eight patients, having 46 cataracts, were tested more than two times, the shortest interval between the first and last test being one and a half month, longest ten years, average sixteen months. Of the 87 cataracts 17 showed no change in the vision, but only one of these was tested more than twice. Three cases showed improvement of V., then failure; 8 showed failure, then improvement; 31 showed improvement with no failure of V., making in all 42 cases showing improvement of V. during the time of observation, as against 28 cases showing progressive failure. The number of cases showing progressive improvement and the number showing progressive failure of those which had had more than two tests was exactly equal; 17 of each. In 38 cases the refraction was determined—22 were hyperopic, 15 myopic, while one was anisometropic. In this latter case, however, the hyperopic eye (+ D. 1) became gradually myopic, the highest myopia noted ($-\frac{1}{24}$) being attained in two years four months, V. without correction dropping from $\frac{20}{XL}$ to $\frac{20}{C}$, corrected from $\frac{20}{XX}$ to $\frac{20}{XL}$. Eight patients showed increase of myopia or decrease of hyperopia, as against 4 showing decrease of myopia, or increase of hyperopia. In 35 cases the nature of the cataract was noted, the remainder being, it is fair to presume, all, or nearly all, ordinary senile cataract. The most interest attaches to the cataracts diagnosed as incipient, for these were mostly of the equatorial variety, the kind that it has been claimed have shown such good results in the treatment by electricity. Of 17 of these, 7 showed improvement, 3 myopic, 3 hyperopic, 1 in which the refraction was not noted. Four of these had mature cataract in the other eye; 7 showed stationary V., 6 hyperopic, 1 myopic, 1 not noted. One of these had mature cataract in the other eye. In 3 the V. became worse, refraction not noted, mature cataract in the other eye in two.

Of 8 cases noted as nuclear and peripheral, the V. of 3 improved, 2 myopic. The 5 that showed failure were all hyperopic. Three lenses had cloudy anterior lamellæ; 2 (myopic), showed improvement; 1 (hyperopic) with mature cataract in the other eye grew worse. Two nuclear cataracts became worse. One other showing improvement is noted as striated. Two lamellar cataracts show one stationary, one improved. I shall refer to this later. One cataract was diagnosed as nuclear and sectional; the eye was myopic, and the V. showed improvement. The last of these, a traumatic case, deserves a more detailed description.

The patient, a middle-aged laborer, received an injury to each eye, producing in each traumatic cataract. V. O. D. $\frac{20}{CC}$; V. O. S. $\frac{20}{LXX\ -}$. The right cataract gradually matured, and about three years later was extracted. The V. of the left eye improved to $\frac{20}{L\ -}$ in eighteen months, but six months after this the eye was again injured, the cornea being lacerated and the anterior chamber filled with blood—V. = light. As the blood was absorbed, the cataract, an opaque patch, was seen to occupy the temporal portion of the lens. In eleven months the V. reached $\frac{5}{C}$ + and in two and a half years $\frac{20}{C}$ —. Then failing gradually up to the present time it reached the V., fingers at six inches, ten years and more after the first injury. The lens is almost entirely opaque and neither nucleus nor soft lens matter can be made out. A curious fact to be noted is, that in the cases in which the cataract in one eye had matured, the mature cataract was in the right eye in 9, in the left only in 5.

The cataract in which the V. at any time was over $\frac{20}{CC}$, and showed steady improvement, were (Dr. Noyes's cases):

$\frac{20}{CC}$ to $\frac{20}{XL}$ in seven months.

$\frac{20}{XL}$ to $\frac{20}{XXX}$ in seven months.

$\frac{20}{XL}$ to $\frac{20}{XXX}$ in three months.

Incipient:

X.* $\frac{20}{XL}$ to $\frac{20}{XX}$ in four months.

XVI. $\frac{20}{XL\ -}$ to $\frac{20}{XXX}$ in eleven months.

XVII. $\frac{20}{C}$ to $\frac{20}{LXX}$ in three months.

XXIV. $\frac{20}{L}$ to $\frac{20}{XX}$ in eleven months.

XXIX. $\frac{20}{C\ -}$ to $\frac{20}{LXX\ -}$ in six weeks.

XXXIV. $\frac{20}{L\ +}$ to $\frac{20}{XXX\ +}$ in nine months.

XLVIII. $\frac{20}{L\ -}$ to $\frac{20}{XXX\ -}$ in four and a half months.

XXXV. $\frac{20}{CC}$ to $\frac{20}{L\ +}$ in nine weeks.

XLV. $\frac{20}{LXX}$ to $\frac{20}{XL\ +}$ in five weeks.

LXIII. $\frac{20}{LXX}$ to $\frac{20}{XL\ -}$ in three and a half months.

XXXIX. This improvement is evidently only apparent, and I give it in full: V. O. D. = $\frac{20}{CC}$; with sph. + $\frac{1}{30} = \frac{20}{70\ -}$. Ten days later, V. O. D. = $\frac{20}{CC}$; with sph. + $\frac{1}{16} = \frac{20}{XXX\ +}$.

* Refers to numbers in original tabulation.

Cases which seem to demand special mention are II. $\frac{15}{XXX-}$ to $\frac{15}{XX-}$ in four months. This is the only one of my cases in which it could be claimed that the pathological process showed any improvement. The refraction became more myopic, and I could see the fundus more distinctly. The conditions of light illumination were similar at each time of testing. The V. of the other eye improved slightly. The case was one of cloudy interlamellar substance, and the improvement of V. was not permanent.

XXII. In which a "Förster" was done to ripen the cataract, which was maturing very slowly. After the iridectomy the optic nerves were found to be atrophic, and the V. improved from $\frac{1}{CC}$ and $\frac{2}{C}$ to $\frac{20}{CC}$ and $\frac{20}{C}$, Dr. Bull ascribing the improvement to clearing of the lens substance.

LII. V. O. D. $= \frac{5}{CC}$, after atropine $\frac{20}{CC}$. Nuclear and peripheral cataract. Iridectomy for ripening one week later, V. O. D. $= \frac{20}{CC}$; six weeks later, ditto. On the strength of the connection between ergot and cataract, gtt. xx. of ext. ergot fl., ordered t.i.d. Nine days after V. $= \frac{20}{CC}$, but can be improved to $\frac{20}{C}$ with sph. $-\frac{1}{48}$. In two months the same glass gave $\frac{20}{LXX-}$, but in four months $\frac{20}{CC}$ again, when it is fair to presume the patient went after a doctor who could understand his case, for the record ceases.

LXXI. A girl, sixteen years old, applied to Dr. Tully for treatment at the New York Eye and Ear Infirmary September 7, 1890. She had under atropine V. O. D. $= \frac{15}{XX}$, after correction with sph. + D. 1.25 in either eye; in the right combined with cyl. + D. 1, axis, 180°. She was ordered sph. + D. 1.25 O. D. January 14, 1891 she returned and came under the charge of Dr. Bull. V. O. D. $= \frac{20}{C}$ corrected both before and after atropine. There were punctate and linear opacities in various laminæ of the lens and pulsation of the branches of the central veins visible to the equator. In one month the V. O. D. rose to $\frac{20}{LXX}$ and V. O. S. to $\frac{20}{L}$ with sph. + D. 1.25. There was no change two weeks later than this. The treatment up to this time had been potass. iodid., gr. x. t.i.d. I changed it to pil. hg. chlor. corrosiv. gr. $\frac{1}{8}$ t.i.d., and the V. did not practically change in two weeks more. The right eye could be brought to $\frac{20}{L}$ with a weak concave cylinder over the sph. + D. 1.25. I then discontinued all medicines, and in two weeks V. O. D. was $\frac{20}{LXX}$ with sph. + D. 0.75 $= \frac{20}{L}$, and V. O. S. was $\frac{20}{L}$ with sph. + D. 0.75 $= \frac{20}{XXX}$. No one who has examined the case doubts the improvement in the condition of the lens, although some of the spots and striæ may still be seen at its periphery.

It would be absurd to claim that improvement in the cataract was the cause of the improvement in V. in all of the thirty-one cases where the V. did not at any time deteriorate Changes in the illumination, or going toward the patient with the test card at the first examination, and receding from him or her at the second, will explain some cases. In one case of Dr. Bull's V. rose from perception of light to $\frac{20}{CC}$ upon the removal of a dislocated lens from the other eye. Changes in the pathological process may cause improvement of V. without any improvement of the cataract. Improvement in the irregular lenticular astigmatism has heretofore been suggested as an explanation of this. In calling attention to one cause which, I am satisfied, frequently obtains in senile cataract, let me refer to the case of lamellar cataract before mentioned. The patient was a man forty years of age. The vision in the better eye remained absolutely stationary at each test, but after two tests showing $\frac{25}{CC}$ in the worse eye, in eleven months the V. equalled $\frac{15}{C}$ tested with the same conditions of illumination by means of several test-cards. In this case there were interstices of clear lens matter between the opacities. There can be no doubt that the process was absolutely stationary, and the image must have been thrown upon a more favorable portion of the retina through a different space of clear lens matter than at the first examinations. The record of one case of Dr. Bull's, tested five times in six months, shows most variable results. The diagnosis was eventually made of stationary lenticular opacities, the opacities being radiating ones similar to the spokes of a wheel. This case is not included among the ones which I have tabulated. The application of these observations to the cases of ordinary senile cataract, beginning by a separation of the nucleus from the lamellæ, and later having opaque spots and striæ, is so evident that it is not necessary to carry it to its conclusion. It is fair to presume that nobody would be guilty of changing the illumination from the side of the patient to the back to show improvement in nuclear cases, and *vice versa* in peripheral cataract. From twenty-three cases tested both before and after atropine, which I have tabulated, I am satisfied that a careful and proper arrangement of the illumination, to produce either dilatation or contraction of the pupils in suitable cases, would result in apparent improvement of V. almost at the will of the examiner.

Keeping in mind the manifest liability to temporary improvement of V. in many cases of cataract, let us imagine the medical enthusiast as he obtains a case of cataract and conceives a method of treatment at about the same time. What more natural than that the treatment will cure the cataract. Hurriedly testing the V. he applies, or orders the treatment. The V. on the G. K.H. card has reached, say $\frac{20}{L}$, but Y. K. N. A. 4. $\frac{20}{LX}$ has not been surmounted. After an interval of time the patient returns. "Do you not see better, Mrs. Brown?" "Oh yes, doctor." "Try the test-card." The bright star of hope has arisen and sheds its beams full on the XL line, V. A. Z. B. D. on a bright new card. Perhaps easier to read, but giving $\frac{20}{XL}$ all the same. The patient reads it, and improved V. is shown. Then the ophthalmoscope is used, and of course the cataract has improved. Even the patient is willing to acknowledge that.

There are unfortunately a few details still to be attended to after this improvement of V. has been shown. In the first place the case must be proved to have been one of cataract; secondly, something more than a mere statement is necessary to prove that it has been improved, or cured. Perhaps after these two things have been settled beyond cavil, it would still be well to show the efficacy of the treatment by showing that cataracts not treated at all, or treated by any other method, do not show such good results as these special cases.

The statistics that I have presented to-night do not essentially conflict with the generally received ophthalmological, or pathological opinions concerning the course of cataract. There is, however, one moral to be drawn, ophthalmologists can not be too guarded in giving prognoses in cataract cases, and must not so frequently overlook the fact that the peripheral, or equatorial form of incipient senile cataract may progress so slowly, espec-

ially in myopic eyes, as to be practically stationary. For in many of these eyes the course of the cataract would seem to follow more or less the course of the choroidal degeneration upon which, it is perhaps not too much to claim, the lenticular degeneration may depend.

Nothing remains but to formulate a few statements regarding the course of cataract. 1. It is the rule for senile cataracts to show improvement of vision at some time during their course. 2. It is the exception for pathological changes to remain absolutely stationary, to permanently improve, or to disappear. 3. There is as yet no proof that senile cataracts which have involved the lens nucleus have entirely cleared, leaving normal lens fibres. 4. There are opacities involving the equatorial region of the lens which, in certain cases, can not be differentiated from incipient senile cataract by means of the ophthalmoscope alone, which may be stationary. 5. To repeat the opinion of 1857, before cited, slightly modified: "There does not exist in the annals of science one authentic proof that (true senile) cataract has retrograded, or been arrested in its course under the influence of any medical treatment whatever."

118 East Seventy-second Street.

SOME CLINICAL OBSERVATIONS AT THE ST. FRANCIS HOSPITAL.

By A. SEIBERT, M.D.,

Professor of Diseases of Children, New York Polyclinic, Visiting Physician to St. Francis Hospital, and Physician to the Children's Department, German Dispensary.

I. *Diuretin*, or theobrominum natrio-salicylicum, is a combination of theobrominnatrium and salicylic soda, found and first used by Chr. Gram. He was instigated to experiment in combining these remedies by the researches of von Schroeder, who had demonstrated by tests on animals that caffein and theobromin both had unfailing diuretic virtues, even when given in small doses, evidently due to direct action upon the kidney epithelium. Furthermore, it was found that theobromin had no effect upon the central nervous system and the vaso-motors, while caffein caused contraction of blood-vessels by irritating the vaso-motor nerves. Gram's trials of pure theobromin proved the necessity of altering it so as to make it more soluble and less nauseating to the stomach, and his experiments resulted in the combination called diuretin.

Since Gram's report on the action of diuretin in nephritis, and cardiac derangements impeding circulation so as to cause œdema and ascites, Reisler, Koritschoner, Konindjy-Pomerantz, and Hoffmann have published observations sufficiently favorable enough to induce me to give this remedy a fair trial, and so it has been used by me in the St. Francis Hospital and in private practice, from January 1st to July 1st, of this year.

It would take too much time and space to mention all cases in which diuretin was given, and therefore I will but describe one case of each category.

(*a*) *Acute Nephritis.*—Male, aged thirty, alcoholic history. Admitted January 10, 1891. On December 27th patient had noticed shortness in breathing, swelling of feet, and diminution of urine. On admission he presented hypostasis of left lower lobe of lung, marked œdema of face and lower extremities, scanty urine, fifty per cent. albumin (by volume), hyaline and granular casts. Ordination: Diuretin, 10.0 (⅓ ounce), aq. destill., 180.0 (6 ounces), a tablespoonful every two hours.

Quantities of urine (for twenty four hours) in ounces:

January 12th	Diuretin.	= 38 ounces.	January 18th	=	87 ounces.
" 13th		= 42 "	" 20th	=	94 "
" 14th		= 48 "	" 21st	=	98 "
		58 "	" 23d	=	110 "
		76 "	" 25th	=	116 "
			" 26th	=	119 "

On February 6th all œdema had disappeared; albumin present in but small quantity; general condition much improved; lungs clear; appetite good. Discharged at request. During the test the same moderate quantity of fluids was given. Pulse strong and normal since day after diuretin was all taken.

(*b*) *Nephritis Chronica.*—Male, aged thirty; general œdema. Pulse 96.

Quantities of urine in ounces, from June 1st to 27th, diuretin (10 to 180) taken on June 2d, 3d, and 4th: 24, 11, 12, 18, 14, 17, 20, 22, 29, 36, 71, 66, 84, 69, 73, 67, 90, 113, 116, 137, 115, 110, 67, 68, 55, 35, 63, 41, 64, 56, 67, 82, 72.

June 27th.—Albumin and œdema have disappeared; appetite good. Pulse normal, strong, and full since third day after diuretin was taken.

(*c*) *Stenosis Aortæ, Insuff. Valv. Mitralis.*—Male, aged fifty-three; albumin; general œdema; bronchitis; pulse 110; hypostasis; dyspnœa; alcoholic history. Admitted June 15th.

Quantities of urine in ounces from June 16th to July 1st: 27, 22, 28, 34, 52, 67, 84, 98, 110, 126. June 27th, œdema has disappeared; pulse has become normal, strong, and full, improving twenty-four hours after diuretin was taken; no albumin.

General Remarks.—In all cases an even quantity of fluid was given to the patients. It is of importance to note that the diuretic action of the drug increased from day to day, until two to three weeks after it had been taken, thus showing that the irritation or stimulation of the kidney epithelium continues for a long time—to my mind one of the greatest virtues a remedy can have. In a number of cases of fatty heart, cirrhosis of liver, and far advanced cases of parenchymatous nephritis (where but little epithelium was left in the kidneys), no action appeared from this drug at all, even though the above dose was repeated four to six times within a few weeks; with other cases in private practice I have in all given diuretin to twenty-five patients, and can sum up my notes in the following: Diuretin is a powerful diuretic in doses of ten to twelve grammes given in forty-eight hours, in cases of valvular heart lesions, acute and chronic nephritis. It is also an excellent heart stimulant, increasing blood-pressure, reducing abnormal frequency, and correcting irregularity of heart action. No bad effects were ever noticed, and even not there, where ten grammes were given repeatedly without the desired effect. Naturally, wherever diuretic action appears the heart's action improves, and where the one fails the other does also.

In accordance with other observers, no action whatever was noticed by me from this drug in cases of cirrhosis hepatis, fatty heart, aneurysma aortæ, and in far advanced cases of chronic nephritis, so that the latter fact may be of use for prognostic purposes. As Geisler also had prompt action in a case of acute scarlatinal nephritis in an adult, this new remedy will undoubtedly be used with much benefit in acute nephritis following infectious diseases of children (scarlatina, varicella, pneumonia, morbilli, etc.), because it may safely be employed with benefit to kidneys and heart.

II. *Camphoric acid* has lately been recommended for the night-sweats of phthisis,[1] but before this had been employed with much benefit in purulent cystitis and pyelitis, showing a decided "antiseptic" action. For the last two years this drug had given me much satisfaction in the treatment of purulent cystitis (gonorrhoica), pyelitis, and bronchitis, reducing the number of leucocytes and of the bacteria in the secretions of the respective mucous membranes, as well as stimulating the heart's action. I therefore decided to give camphoric acid an extended trial in those forms of bronchial catarrh and broncho-pneumonia complicating and follow-

[1] Leu: Wien. Med. Woch., February 6, 1890.

ing the severe attacks of influenza. It was given in powder form, eight grains three to six times a day, the latter being exceptional.

The cases of influenza received at the St. Francis Hospital during my service (January 1st to July 1st) were all complicated by more or less severe bronchitis, particularly of the capillary variety, consolidation of the right base, and often of both. Two-thirds of our patients were men, and of these at least two-thirds were habitual topers, whiskey being used more than beer. I do not intend to bring statistics more than to state that we had but four deaths from influenza-pneumonia. The best time to begin with camphoric acid in these cases appeared to be when the secretion of the mucous membrane of the respiratory tract had a yellow purulent character, the tongue was dry and furred, the odor *ex ore* fetid, the heart weak, the pulse thin and fast (120 to 150), consolidation complete, the dependent bronchioli full of mucus, and respiration labored.

The first signs of improvement after giving camphoric acid were noticed invariably on the tongue and in the bronchi. The fetid odor subsided after two days; the tongue became moist, the fur receding, and the small, dry, crepitant râles gave way to vesicular breathing and large moist râles; the expectoration increased, large quantities of muco-pus being coughed up. The area of dulness gradually diminished in size, but usually, long before it disappeared entirely, the patient's tongue would be clean and moist, and appetite—this most wished-for of all symptoms in such tedious cases—would appear.

In private practice I had to record one death, in a female, aged sixty, who had suffered for years from fatty heart, emphysema, and bronchitis. In the hospital one of our patients, besides capillary bronchitis of both lungs, even of the apices, had areas of dulness extending from the right apex back to the base and forward to the mammilla, on the left from the base upward to the scapula and forward to the axillary line; the respiration accordingly near 40, and the pulse usually 144 to 150 per minute, the feebleness of the heart-muscle ultimately producing embolism of the right femoral artery. Eight grains of camphoric acid, given six times a day at this critical period, had a most marked effect, and the man made a complete and comparatively speedy recovery.

To my mind camphoric acid is a most valuable remedy in disinfecting the mucous surface of the respiratory tract. Bad effects like nausea or loss of appetite were not noticed; on the contrary, the powder was always well taken and retained without complaint. To avoid being misunderstood, I wish to here state distinctly that I do not consider camphoric acid a specific in bronchitis and pneumonia of influenza, but a most valuable internal disinfectant of the bronchial mucous membrane. In the night-sweats of phthisis I usually give fifteen grains at 8 P.M., and in the few cases we have at the hospital it had the desired effect in about four-fifths of the cases. This dose also never gave rise to any visible unfavorable symptoms, nor to complaints on the part of the patients.

III. *Rectal Administration of Salicylic Soda in Inflammatory Rheumatism.*—In an article on "Rectal Medication," published in the *Medicinische Monatsschrift*, April, 1889, I was the first to point out the necessity, value, and expediency of giving the salicylic soda in solution per rectum. For the last five years it has been my habit in private practice to order this drug to be injected into the rectum, instead of giving it by the stomach. Nearly all our remedies entering the stomach cause more or less irritation, some loss of appetite, others distention, distress, and nausea. Salicylic soda ranks high in the latter class.

Occasionally we meet with patients who appear to have no ill effects from large, frequent, and protracted medication upon their stomach digestion, but I venture to hold that this only appears to be so, and then only to the superficial observer. In acute attacks of rheumatism it is of the utmost importance to give large and frequent doses of salicylic soda, so as to check the career of the rheumatic germs as soon as possible, and thus (unless the mischief has already been done) to prevent an endocarditis. The experience I have had in the administration of this specific anti-rheumatic remedy per rectum, particularly in children, justifies me in claiming that this imperative indication can be much better followed by giving the drug per rectum than by the mouth. Aside from the fact of frequently producing nausea, increasing the paucity of digestion, and causing distress, and very soon most marked adversity to this medication in the patient, it is a fact that more of the drug is absorbed and in less time per rectum than when given per os in acute attacks. In those hospital cases where gastric disturbance was caused by salicylic soda in the stomach, rectal medication was resorted to, and usually with much better effect. In fresh attacks in adults we have given twenty grains of the soda every hour, during the first twelve hours, six doses the next day, etc. In but very few cases signs of tenesmus appeared, and only after long-continued treatment in the more chronic varieties. To illustrate, I can record the case of a boy of five years, who had been in bed for six months with swollen knees, ankles, toes, and finger-joints, almost reduced to a skeleton, with marked anæmia, mitral insufficiency, and such an irritated stomach that the very sight of a medicine-spoon made him vomit. This child was given, from March 21st to April 12th (according to the record of the druggist), 608 grammes (20¼ ounces) of the salicylic soda per rectum, the prescription being natr. salicyl., 8.0; aq. dest., 180.0, every two hours a tablespoonful. The result was that by that time (after three weeks of treatment) the boy could ride a tricycle for the purpose of exercising his joints and muscles, the pain having left him after the first six doses, and his appetite returned never to fail again. Aside of muriatic acid and pepsin, this little patient had taken no medicine by the mouth, a weak solution of the iodide of potassium being also given per rectum. In hospital practice rectal medication involves time and labor, but in private practice salicylic soda may be given per rectum as well as antipyrin, with much benefit to the patient and the practitioner.

IV. *Irrigation of the Colon in Typhoid Fever.*—Since Backhaut, at Mosler's clinic,[1] first recommended irrigation of the colon with a five per cent. solution of tannic acid, I have made use of this method, with the modification of using plain warm water instead. The limited number of cases of typhoid fever seen at the hospital, treated by this method of washing the colon two times daily, giving the proper diet and some muriatic acid and pepsin per os, have made speedy recoveries.

To my mind the value of flushing the colon at regular intervals is in cleansing it. No doubt the constitutional symptoms of typhoid are due to absorption of impurities (pathogenic germs and their products) from the diseased intestines, as vomiting and diarrhœa in summer complaint (better called "milk-poisoning") of infants and young children, is due to the presence of decomposing food in the alimentary canal. We can wash out the stomach of an infant and check nausea (provided œdema of the brain and meninges has not yet developed), and we can clean the colon two to three times a day, and thus materially aid in cleansing the bowel of pathogenic germs; and so we can clean the colon of the typhoid patient and prevent the accumulation of typhoid and other bacteria and their absorption from the colon.

If cleansing of the colon is resorted to in the early stage of typhoid, we first notice its beneficial effects upon the nervous system. In all of my cases insomnia disappeared after the first two washings. If the case comes in hand in the second or third week, a decline of temperature usually follows the first irrigation. Statistics amount to nothing in typhoid unless very large figures are given; but if in every case of a limited number the beneficial effect of a certain course of treatment has appeared the same night and the next day, and improvement has been steady since, then even a small number of

[1] Deutsch. Med. Woch., July 18, 1889.

cases may venture to speak for itself. Since adopting bowel-washing I have had no deaths. My youngest patient was twelve, and my oldest seventy-seven years of age; a son of the latter had died of typhoid under another's treatment two months before his mother took sick. In the boy, the first patient I ever employed this treatment on, a hemorrhage occurred after washing his bowel for six days, and after all severe symptoms (temperature of 105° F., profuse diarrhœa, delirium, and insomnia) had disappeared, which led me to desist from further injections in this case. In our cases at the hospital the temperature invariably was lower the next day after the first irrigation, the normal usually being reached from 104½° F. to 105° F. in from six to eight days.[1]

Regarding the diet of typhoid patients, I must here admit that I am no friend of the so-called milk-diet. Typhoid is a disease of the intestines, causing high fever and general symptoms by the absorption of pathogenic material from the intestine. If milk-diet is not justifiable in the ordinary "catarrhal" intestinal disturbance of the adult and infant, why, then, should it be so where a well-known typical form of intestinal disease is before us? If we feed the bacteria more than the child in intestinal catarrh by giving milk, why, then, do we commit the same error in typhoid by giving this food? In both affections we have decomposition of food in the intestine; in typhoid as well as in summer-complaint we may observe nausea, vomiting, distention of stomach and intestines, increased diarrhœa and rise of temperature after the administration of milk. To put lime-water in the milk does not prevent its later infection in the intestine, nor does its sterilization. If we discard milk in intestinal catarrh and enteritis, why not in cases where we have almost entire suspension of digestion, assimilation, and absorption of food, and a large quantity of pathogenic fermenting material passing over typhoid ulcers? Reflections of this kind have forced me to discard milk entirely as a food in typhoid fever. Boiled soups of rice, dried peas, oatmeal, lentils, and barley, and cold water, tea, and coffee *ad libitum*, have served my patients well. The soups are only given three times a day. Distress and tympanites caused by development of gases have never since troubled my patients in typhoid fever.

Clinical Department.

SENILE GANGRENE—AMPUTATION—RECOVERY.

By GEORGE S. HARKNESS, M.D.,

STOCKTON, CAL.

I HAVE been induced to report the following case for the reason that it is somewhat rare, and that the treatment was not exactly orthodox.

Philip H——, seventy six years of age. I was called February 19, 1891, and found the patient complaining of a severe pain in the little toe of the left foot. He had been suffering for about two weeks, during which time the pain had been severe enough to prevent sleep, and, as he said was "getting worse all the time." Attributing the trouble to a bad corn, he had applied the various cures to be had in the shops, but not obtaining relief had concluded to discharge the druggist and hire a physician—to change doctors, as it were.

On examination I found that although the patient complained of severe and continuous pain, firm pressure over the part did not noticeably increase his suffering. The toe itself was evidently somewhat anæsthetic, for an incision carried down to the bone occasioned no complaint and caused little or no hemorrhage. I ordered hot fomentations and an anodyne, and told him that I would call again in a few days. By that time discoloration had supervened and established the diagnosis.

The pain was intense. To control it, he had to be kept pretty well under the influence of morphine—so much so that the family objected to its use, complaining that it caused delirium. I tried other anodynes, but to no purpose. One thing peculiar in this connection was that he could not endure hot applications, and he was more comfortable with the foot depending than elevated

March 16th.—A line of separation having measurably formed, I amputated the toe. My reasons were twofold:

1. I was in hopes of affording some relief to the pain. 2. He had had one or two chills followed by fever, so that I feared septic absorption, and thought that the wound might afford some drainage. In neither, however, was I successful. The pain continued as before—excruciating, agonizing. The tissues were hard and boggy, and little or nothing escaped from the wound, although it was dressed open. Discoloration began to appear in the adjoining toe and extended into the arch of the foot. I cut out a portion of the metatarsal bone, and made openings higher up, introducing drainage-tubes, but the discharge from them was very slight. The gangrene showed no indication of limiting itself, and as he could not endure fomentations and insisted on keeping his foot depressed, there seemed nothing to do but to give anodynes and to wait. He continued, from time to time, to have chills, followed by fever and sweating. The administration of quinine did little or no good.

April 3d.—Without waiting longer for the line of demarcation, which as yet gave no signs of forming, and with the assistance of Drs. Payton, Ruggles, and Gibbons, I amputated the leg at the junction of the middle and lower thirds. There was considerable trouble from hemorrhage, inasmuch as the posterior tibial artery was atheromatous and very brittle, the artery tearing in the grasp of the forceps, and the ligature cutting through without occluding the vessel. It was finally included with the surrounding tissue and the hemorrhage controlled. The patient bore the anæsthetic well, and rallied promptly from the operation.

The first dressing was on the fourth day. There was discoloration around five or six of the stitches, about half an inch in diameter. I had tried to do an aseptic operation, but the location and surroundings were unfavorable, and I found considerable pus and blood oozing from the wound. In company with Dr. Payton I removed the stitches, and from that time on it was dressed open. The gangrene did not extend, and in about two weeks the sloughs separated, leaving a healthy granulating surface. Another, which had appeared over the crest of the tibia, also separated about the same time. Subsequently two large sloughs formed, extending up into the leg, one anteriorly and the other posteriorly, but whether caused by the burrowing of pus or an extension of the gangrenous process, I am unable to say. After removing the dead tissue, the cavities were opened and drainage-tubes passed through to the wound below. They gradually closed, and the tubes were removed about May 20th.

May 26th, he left for his home in Arizona. The wound was not entirely healed, but all suppurating cavities were closed, and there was a healthy granulating surface over the stump, nearly or quite two-thirds of which was covered with epidermis. I have had one letter from him, in which he states that he is improving, though not entirely well.

I consider the above operation justifiable on the following grounds: 1. The relief of pain. This of itself ought to be sufficient, for pain alone will destroy life. In this case the pain had been intense, unbearable, continuous, and only yielded to full doses of morphine. After amputation he suffered practically nothing, and the use

[1] The ordinary fountain-syringe is used for rectal irrigation, the buttocks of the patient being elevated, so as to facilitate the flow of the water high up into the colon. Rectal tubes or catheters are unnecessary, and may do harm in reaching typhoid ulcers of the colon.

of anodynes was discontinued. 2. The occurrence of chills indicated the absorption of the septic material. Drainage by incision and tubes had proved of little service, for the reason, I suppose, that vital processes are carried on slowly in tissues imperfectly supplied with blood. Amputation, therefore, afforded the only certain method of removing the source of infection. 3. It conserved the patient's strength and gave him the only chance of ultimate recovery. Although a man who carried his years fairly well, and was inclined to boast of his physical strength, he had become very much reduced. After the operation he rested well and his appetite improved continuously, although there was for several weeks an extensive suppurating surface.

It is easy enough to recognize our own mistakes after they are committed. 1. In this case amputation might have been performed at least three weeks earlier. Nothing was gained by delay, and the exhaustion consequent upon the pain and sepsis was marked. 2. The wound should have been dressed open. The stitches were not tight enough to produce strangulation under ordinary circumstances, yet they caused so much gangrene that the flaps were hardly sufficient to cover the end of the bone. It became necessary, therefore, either to perform another operation or to rely upon granulation. Fortunately the latter proved sufficient. 3. There might be some question as to the point of election in amputation. We decided that there was but little choice between the ankle and the knee. We were above the main arterial branches passing to the foot, and little could be gained by a higher operation, unless it were above the subdivision of the popliteal artery at the knee-joint.

TWO CASES OF SUSPECTED SYPHILIS, THE DIAGNOSIS BEING VERIFIED BY TREATMENT.

By DORSEY M. McPHERSON, M.D.,

WASHINGTON, D. C.

In September, 1889, I was consulted by Mrs. D—— in regard to some tumors which had made their appearance on the left elbow and right instep. She had just returned from New York State, where she had gone for treatment for a cancer of the upper lip, which she said had been so diagnosed by two physicians, one in this city and the other in Philadelphia. I found an elastic growth over the olecranon process of the left ulna and a like growth on the astragalus of the right foot. I also found a tender purplish spot, about the size of a half-dollar, over the crest of the right tibia. My suspicions became aroused, and I more carefully examined the so-called cancer. It was then in a very highly inflamed condition, the result of a caustic paste which had been used in the recent treatment. There were hard nodules along the mucous surface of the lip, which she said resembled the cancer when it first started. The gums were very red and spongy, and upon pressure a quantity of pus was forced up about the teeth. I told her I believed the trouble was not cancer, but due to a blood disease of another character, diagnosing the condition as gummatous ulceration of tertiary syphilis. I prescribed iodide of potassium in fifteen-grain doses and biniodide of mercury one-sixteenth grain three times a day. The dose of the iodide of potassium was after three days increased to twenty grains. After three days' treatment the gums began to improve, no more pus could be forced up, the wound on the lip commenced to heal, and at the end of the third week the tumors had entirely disappeared, together with the tibial tenderness and inflammation. The treatment was continued over a period of eight months, with occasional intermissions. At this date, after eighteen months, there has been no return of any symptoms of the disease.

The husband of this patient met me on the street about March 1st of the present year, and in conversation incidentally mentioned that he was suffering from great drowsiness, in fact could not keep awake. He being somewhat constipated, I told him to take cathartics and more exercise and he would feel better. On March 13th his wife came for me, and said he was in a stupor. I found him on the bed, apparently enjoying a peaceful sleep. By talking in a very loud tone I could rouse him sufficiently to get an answer to a question, but he would at once fall asleep and sometimes would not complete a sentence. His wife informed me that he had been in a sleepy condition for several weeks, would fall asleep at the breakfast-table, and that morning he arose as usual and kindled the fire in the kitchen range, but instead of putting on coal he had gone to the shed and filled the coal-hod with ashes, which he dashed upon the fire. He then went to the water-closet and sat on the stool without removing his clothing, consequently defecating in his clothing, yet perfectly oblivious of the fact. (He is a man of refinement and education.)

I suspected that the possible use of narcotics might account for the great somnolence, but I was not satisfied that it was a cause of the insane acts; then, too, the wife assured me that he was not in the habit of taking drugs. I noticed that his pupils did not respond readily to light, yet were not abnormally contracted nor dilated. I did not prescribe for him then, but told his wife to let him sleep, and I would call in the morning—this was about 10 P.M. After leaving him I recalled the fact that he had met me on the street and told me of an attack of severe headache, accompanied with double vision, also some ataxic symptoms, to which I did not at the time give much weight. When I saw him the next morning, Saturday, March 14th, I found him up and dressed; he recognized me and said he was glad I had stopped in, as he had a severe headache, for which he would like me to prescribe. He talked at random, had a wild expression, and could not recall any events happening since Thanksgiving Day, which he said was on the Thursday preceding. His wife told me that he had been talking all the morning in the most disconnected manner about imaginary events. In taking the whole history of the case into consideration as I had observed it, together with the wife's past illness, I believed I had a syphiloma of the brain to deal with, and that my syphilitic treatment must be pushed vigorously if I hoped to do much good. I accordingly prescribed iodide of potassium in thirty-grain doses three times a day (using trifolium compound as a vehicle). On the third day after beginning treatment he began to realize that he was not right in his head, as he expressed it. He then was aware that he had not been at his office as usual and that there had been a blank. He still suffered from severe frontal headache, worse after 5 P.M. When talking to him on the fourth day he cried like a child, sobbing aloud, the outburst being not unlike an hysterical attack.

On this day, the fourth, I increased his iodide to one hundred grains a day and added one-sixteenth grain of bin iodide of mercury three times a day. His headaches continued and his mind was a little flighty for about a week, when the headaches gradually ceased, his eyes took on a natural expression, and he returned to his desk, apparently well, expressing himself so, and has remained so to this time, over two months since treatment commenced. He is now taking one hundred grains of iodide of potassium and one-sixteenth grain of the biniodide of mercury as first prescribed. It has caused no stomach disturbance and but a slight eruption.

The history of both cases is herewith submitted, told in the man's own words. It will be observed that there is no history of the primary sore in the wife's case, neither can it be elicited.

I was married in the winter of 1876; my wife was apparently then a healthy woman, never having been seriously ill, except in 1874, in New Orleans, when she had a severe attack of pneumonia.

About five years after our marriage I noticed that she had a cutaneous eruption upon different parts of her body,

near the joints, knees, elbows, and wrists, and through the scalp, similar to that upon my own person. She was otherwise apparently healthy.

In 1885 a small spot or hard pimple appeared at the left hand corner of her upper lip. On consulting Dr. ——, he pronounced it an epithelioma, treated it during nearly three years with caustics, but it increased and continued across the upper lip. She then resorted to some other kind of caustic treatment (unprofessional), which was continued nearly a year. About this time there appeared upon her left elbow and right foot certain swell ings or tumors. These gradually subsided and in about three weeks entirely disappeared, and the spot on the lip eventually healed up, and has entirely disappeared. During this time she was under treatment with iodide of potassium. There has been no local appearance of the disease for over eighteen months.

In July, 1886, she had her last full menstrual period. It ceased entirely after that date, though she was just past thirty years of age. She has never shown signs of pregnancy. She still has the cutaneous eruption upon various parts of the body, but has not resorted to any particular medical treatment of late to remove it. It disappears to some extent during the heated term, but returns in winter. It is never inflamed or sore. She has complained lately of rheumatic or sciatic pains of the lower extremities, but beyond an extreme nervousness, due probably to her previous treatment, she appears to be in fair health.

Sometime in 1867, when I was but twenty years old, I had a hard spot upon the penis; it was pronounced a chancre and cauterized, and disappeared inside of two weeks, during which time I took iodide of potassium. I neither suffered then, nor had I, apparently, any detrimental effects afterward.

From 1867 to 1871 I had frequent attacks of gonorrhœa, accompanied with gonorrhœal rheumatism. In 1871 I enlisted in the U. S. Army, and was apparently sound and well in every respect. In 1872 I had a severe attack of small-pox, then epidemic, in Philadelphia. I was in hospital fifty-one days, returned to duty, and was well and hearty over two months, when I was attacked with rheumatism, swelling of both feet, the fingers of the right hand, and the shoulders. I was discharged on a surgeon's certificate of disability for "periostitis of internal cuneiform and first metatarsal bones of left foot" in August, 1874.

I became well in time, passed a second physical examination, and was again enlisted in February, 1876, apparently well and hearty.

Had another serious attack of rheumatism in the fall, with much swelling of the lower extremities. Was married in 1876. From 1876 to 1883, beyond rheumatic troubles, had no particular ailment. In 1883 was attacked with symptoms which, I was told by a medical friend, were those of locomotor ataxia, irrepressible hysteria, and an inclination to fall forward when walking. Eventually I was cured of the ataxic symptoms, but the hysteria has continued to a slight extent. Some three years since I was attacked with frequent headaches, occasional periods of inability to reply promptly to questions put to me; although I was fully aware of what reply to make, yet I was unable to speak intelligently, and was as likely as not to make an unintelligent or foreign reply. These attacks were but momentary, and I eventually made a proper reply. I have always had rheumatic attacks, pain, and stiffness of the joints, especially in lumbar region.

On March 13th last, I cannot remember having been unusually out of health, though I have since learned that I had previous attacks of drowsiness or insensibility at my desk, and I had frequent headaches. I became in sensible on my return home and remained in that condition fully forty-eight hours. I lost all memory of past events, though I recognized persons and my surroundings after I recovered sensibility. I have taken over ten ounces of iodide of potassium and five grains of biniodide of mercury. During the past three weeks my severe headaches have entirely disappeared. I have recovered mostly my memory of past events. I am not fully recovered, am rather indifferent to approaching events or to my surroundings. Sleep well, appetite fair, but I must admit to a loss of interest in almost everything, and an utter indifference to final results. Altogether there has been a marked improvement in my general health in the past eight weeks. I can attend to my duties as usual, and only suffer from hysteria occasionally, and an anticipation or rather fear that I may have another attack of mental paralysis.

COLIC NOT A NECESSARY SYMPTOM IN GALL-STONES.

By H. MEEK, M.D.,
LONDON, ONTARIO.

That colic is not always a symptom in gall-stone cases was illustrated by a case which I saw some time ago at the Birmingham Hospital for Women.

A woman, aged fifty-four, presented herself for examination at the out-door clinic of Mr. Lawson Tait with the following symptoms: More or less aching pain in epigastrium, with sickness and loss of appetite. Bowels regular, but stools paler than normal. She had been steadily losing flesh for some time, was slightly jaundiced, and had that cachectic appearance so often seen in malignancy. She had not suffered from colic. Examination of abdomen revealed an indistinct thickening in region of gall-bladder, which Mr. Tait said might be a malignant growth, though he was inclined to think it a gall bladder distended with gall-stones, and advised an exploratory incision. She was admitted to hospital and exploratory incision made over tumor, when diagnosis of gall-stones was confirmed. The gall-bladder was opened and one hundred and twenty stones of different sizes removed, in all weighing two hundred and sixty-five grains.

The absence of colic as a symptom in this case was explained in the operation. A large stone, weighing sixty-five grains, was found at bottom of sac over mouth of duct which prevented smaller stones from getting into duct and causing colic.

A UNIQUE CASE OF SYPHILITIC INFECTION.

Dr. M. Kleiner, of Denver, Col., writes: "Miss C. B——, a female domestic, of good character, consulted me on account of a sore on the upper lip. The appearance of the lesion warranted a diagnosis of chancre, this opinion being verified by the appearance, later on, of the general secondary eruptions and concomitant symptoms. The patient stated she had applied for chapped lips some vaseline, which she found in the room of a young man boarding at the house where she was employed.

"Investigation revealed the fact that the vaseline had been applied to a primary syphilitic lesion of the penis.

"The case is reported as another instance of the many peculiar methods of syphilitic infection."

One Way to Collect a Bill.—A well-known dentist tried hard to collect a bill, but after many ineffectual efforts said to the debtor: "I do not intend to send you any more bills, and I don't intend to sue you; but there is one thing I want to tell you. Every time you cut off a piece of beef-steak and pass it to your wife, I want you to remember that she is not chewing that beef with her teeth, nor with your teeth, but with my teeth." In two or three days he received a check. The notion of those doubly-false teeth in his wife's mouth was too much for the husband.

Progress of Medical Science.

Hemorrhage in Paracentesis Tympani.—Dr. Hildebrandt records the following case of injury to the bulb of the internal jugular vein, following paracentesis of the membrana tympani: A female patient, aged four, complained of sudden severe pain in the right ear. The membrana tympani was found injected and bulging in its posterior inferior segment. Immediately after paracentesis of the membrane had been performed, a large amount of dark colored blood flowed through the incision and from the meatus. It was necessary to plug the external meatus to check the hemorrhage. The membrane shortly afterward presented in its posterior segment a bluish red prominence. This prominence was found to vary at times, and especially so when pressure was made upon the internal jugular vein. Professor Trautmann, in whose clinic the case occurred, believed that the prominence was the bulb of the internal jugular vein protruding through a fissure in the floor of the middle ear.—*The Medical Chronicle.*

Acute Pulmonary Congestion of a Pseudopleuritic Type.—Dr. Berthier says there is a form of pneumonia which gives the signs of pleural effusion, namely, complete dulness on percussion and absence of vocal vibrations and breath sounds. It has been termed by Professor Grancher "pneumonie massive." The ramifications of the bronchial tubes up to the larger divisions are filled with exudation. Professor Grancher has also described another form which yields similar physical signs, and which he has named "spléno-pneumonie." He supposed it to be due to a sero-albuminous and epithelial inflammation. Dr. Berthier reports a case occurring in a young man after influenza. There were signs of fluid at the left base, but exploration with the needle was negative. The expectoration consisted at first of pure blood. On the fourth day the patient became much worse; he was cyanosed. Similar signs were found at the right base, with bronchial breathing and bronchophony at the angle of the scapula. Later, friction sounds were heard over the subspinous fossa, first on the right and later on the left side. The patient was discharged well in six weeks' time. Dr. Berthier remarks that the "congestion" was very intense in this patient; the parenchyma of the lungs was infiltrated with blood, as also the smaller tubes.—*Revue de Médecine.*

Fetor of the Lochial Discharges.—In an article on this subject by Dr. Boxall (*The Practitioner*) the following opinions are expressed: 1. That septic infection may take place without fetor. 2. That fetor may occur without sepsis or fever. 3. That fetor is more frequent in cases where the tissues are bruised and torn, and therefore in primiparæ and in operation cases. 4. That fetor is generally (though not invariably) associated with fever, but in such cases the fever almost invariably precedes the fetor by a considerable interval. 5. That the presence or absence of fetor is a very uncertain guide to the presence or absence of sepsis. 6. That in any case, as fetor invariably indicates a failure to maintain local asepsis, vigorous antiseptic measures should be at once instituted. 7. That the vulva and vagina should be first cleansed, and only when this has been done, and where real necessity exists, should the cleansing be extended to the interior of the uterus.

Instrumental Treatment of Enuresis.—Dr. Sänger, of Leipsic, recommends a course of systematic dilatation of the urethra in cases of enuresis both in women and female children. His plan is to introduce a metal catheter well into the bladder, keeping the thumb over the aperture. The instrument is then firmly pressed backward and to each side from eight to a dozen times. It is, of course, useless to make any pressure anteriorly, as the pubes lies immediately in front. Ten or twelve sittings are usually sufficient. During the treatment the patient is desired to control the sphincter as much as possible by means of the will, to take but little to drink, and to keep the abdomen warm. The good effects of this mechanical system of treatment are to be ascribed to increased power gained by the sphincter in consequence of its contractions after dilatation and stimulation. This method is useful where the paralysis is of central as well as where it is of peripheral origin. Where, however, the neck of the bladder and the whole urethra are of very large calibre, it is useless, and in such cases a plastic operation is required.

Acute Ataxy.—Professor Leyden thinks that there are two forms, the central or cerebral and the sensory form of acute ataxy. Both agree in the sudden onset, the rapid course, and in that they follow on acute diseases. The following are the symptoms of the central form: The speech is slow and scanning, but the tongue is freely movable, there is ataxy without loss of power of the extremities, there are psychical disturbances, but the sensibility is intact. This condition very much resembles disseminated sclerosis, and Professor Leyden is of opinion that it is caused by spots of degenerated tissue in the pons and its immediate neighborhood. Sensory ataxy in many points resembles that form of locomotor ataxy which is associated with peripheral neuritis. This, like the other form, may follow acute diseases, but it may have other causes. Professor Leyden concludes his paper by describing a typical case, that of a man, aged fifty five, who had had syphilis and muscular rheumatism. His acute ataxy appeared to be due to his getting very cold. He suffered from creeping sensations in the legs, numbness of the feet, and ataxy of the lower extremities, loss of both knee-jerks and of the left cremasteric reflex. There was no affection of the upper limbs.—*Zeitschrift für Klinische Medizin.*

The Rise of Temperature in the Epileptic Attack.—In his wide experience of epilepsy at the Bicêtre, M. Bourneville has spent much time in the study of its effects on the temperature, and has come to the conclusion that it always raises the temperature a little at the time of the attack. In the case of single isolated fits, the rise was always clearly perceptible—on an average about 1° F., and sometimes as much as 3° F.; in a series of ten or twenty fits it was on an average larger, about 1.5° F.; and in the cases of status epilepticus there was frequently a temperature of 105° F., and sometimes even of 108° F. M. Duflocq has recently published a few cases of partial epilepsy of subcortical origin, in which only a few observations showed any rise of temperature, which was claimed as abnormal. These have led M. Bourneville to repeat some of his previous lengthy and careful observations. Selecting sixty-seven patients in whom there were single isolated epileptic attacks, he has taken the temperature in each: (*a*) during the stertor immediately succeeding the convulsion; (*b*) a quarter of an hour later; and (*c*) two hours later There is a uniformity in his results which is remarkable. In none of the cases is the temperature at the time of the attack as low as normal, and in none is the temperature not lower two hours later. The average (*a*) in the period of stertor is 100.5° F., (*b*) a quarter of an hour later is 100° F., and (*c*) two hours later is 99.3° F. In nine other cases the rise of temperature culminates at (*b*) 100.5° F. rather than at (*a*) 99.8 F., but sinks at (*c*) to 99.4° F. In that second class of cases in which there are series of attacks with short periods of consciousness between each, M. Bourneville's old observations are found to repeat themselves in four new cases. The temperature after the series of attacks rose on an average to 102.1° F., and fell after eighteen hours to 100.3° F. In the third class, consisting of four cases of status epilepticus which all ended fatally, the rise of temperature was not quite regular during the three or four days that the condition lasted, but rose in all cases over 105° F., and in one case touched 108.4° F. just before death.—*Revue de Médecine.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 12, 1891.

NITROUS OXIDE AND OXYGEN AS AN ANÆSTHETIC.

IN the *American Journal of the Medical Sciences* for August, Dr. William W. Van Arsdale gives a detailed account of his experience with a mixture of nitrogen monoxide and oxygen as an anæsthetic. Nitrogen monoxide alone has been definitely abandoned in minor surgery except for the very shortest operations, such as single incisions and tooth extraction. It produces asphyxia by shutting the oxygen off from the blood; it also produces anæsthesia by its specific action on the blood and nerves. Many experimenters have tried to secure the anæsthetic without the asphyxiating effect. The problem was solved by the late Paul Bert. His method of reasoning, says Dr. Van Arsdale, was this :

Pure nitrous monoxide causes anæsthesia at atmospheric pressure, but also asphyxia. The latter can be obviated by the admixture of as much oxygen as is contained in our atmosphere—*i.e.*, one volume of oxygen added to four volumes of the nitrogen monoxide. If, however, this admixture is made, the tension of the nitrogen monoxide in the mixture is not as great (by one-fifth) as it was before the admixture, and consequently no anæsthesia will be produced. In order to remedy this it is only necessary to increase the atmospheric pressure by just so much as the tension of the nitrogen monoxide gas is weakened by the addition of oxygen, namely, by one-fifth atmosphere. If this be done the result of inhalation will be anæsthesia without asphyxia.

The practical problem presenting itself for solution was how to obtain the atmospheric superpressure. It was solved by Paul Bert by building a hermetically-sealed glass cage with proper arrangements attached for increasing the atmospheric pressure. Into this cage the patient and the surgeons and assistants were all admitted, and here the gas was administered.

The practical obstacles in the way of this method are the expense of the apparatus, which alone amounted to 10,000 francs, and the difficulty of its transportation.

With this arrangement, however, success was manifest. A large number of operations were performed by L'Abbé and Péan.

Subsequent experimenters confirmed in general the views upon which Bert's method was based. A good many tried to use mixtures of the nitrous oxide and oxygen in varying proportion, with only moderate success. Dr. Van Arsdale began his experiments with mixtures containing twenty and fifteen per cent. of oxygen, but the results were not very uniform or satisfactory. They were better with a ten per cent. mixture, and this was the combination finally adopted. The great difficulty in most cases was found to lie in the fact that patients would not breathe deeply. Hence it was proposed to give the gas under a pressure which would force the air into the lungs. This was done by fitting an air-tight mask to the face and placing a board weighted to five pounds on the reservoir bag. It was found that the first bag of gas from the cylinder contained too much oxygen, and it was not used; the last one contained too much nitrous oxide, and caused slight cyanosis. The large cylinders were the better.

The results obtained by using the mixture under pressure as described were in some cases brilliant, but there were also failures, due to nervousness, idiosyncrasies, and perhaps alcoholism.

Dr. Van Arsdale says : "We find the field for the administration of mixtures of nitrogen monoxide and oxygen considerably narrowed down, and are obliged to rule out, as unsuitable, quite an appreciable percentage of all the cases we may be called upon to treat.

"In the majority of cases, however, in young, healthy individuals and in females, the anæsthetic mixture, when administered under pressure, was found to work well and to be much superior to the pure nitrogen monoxide for surgical purposes. It induces a state resembling a quiet, deep sleep, in which the respiration is slow and regular, the pulse regular and full, and not much, if ever, increased in frequency. The blood-pressure is not increased; and insensibility to pain and unconsciousness go hand-in-hand.

"We have," he says, in conclusion, "in the ten per cent. mixture of oxygen and nitrogen monoxide an anæsthetic which may be administered with perfect safety and for a sufficiently long time to permit of the circumspect performance of most minor operations, but one which may be characterized as a weak anæsthetic. For although it will plunge the average adult into a state resembling peaceful slumber, in which anæsthesia and unconsciousness are well marked, it cannot gain victory over states of great nervous excitement or dread, or certain habits or idiosyncrasies."

These conclusions appear to have been carefully worked out, and to present very truthfully the present position of the subject of nitrous oxide anæsthesia.

THE INTERCONTINENTAL AMERICAN MEDICAL CONGRESS.

A MEETING of the Committee on Organization of the Intercontinental American Medical Congress will be held in St. Louis on October 14, 1891, when the time and place of meeting of the proposed Congress will be decided upon. It is needless to say that this will be a most important meeting, for upon its outcome will doubtless rest the success or the failure of the Congress.

As regards the time of holding the Congress, there will probably be little difference of opinion, for it could be held only in 1893. To set any other year than that of the Columbian Exposition for its meeting would be to insure its failure. Our Latin-American confrères would

not make two journeys to this country in successive years, and if they had to decide between the Medical Congress and the Chicago Fair, we fear the Congress would suffer. The fact that the International Medical Congress will also convene in 1893 need not be taken into consideration. Of course, the American Congress should be called for such a time as not to interfere with the International. But if the date of meeting of the latter is not announced before the convening of the American committee, they must set a time, and let the International select some other time that will not interfere.

There will probably be less unanimity concerning the place of meeting, although we think there is but one city where it can be held. Chicago should by all means not be selected. It will be crowded with strangers off on a holiday and devoting their entire energies to sightseeing and amusement, and its atmosphere will not be congenial to scientific thought. Doubtless, all those taking part in the deliberations of the Congress will want to visit the Fair, but they can do this before or after the medical work. Most of the Mexican visitors to the Congress would probably reach this country by rail, but those from the West Indies and Central and South America would all come by sea and, with the exception of a few coming by way of San Francisco or New Orleans, disembark in New York; so that the objection of entailing the fatigue and expense of an extra journey on the members if the meeting were not held in Chicago, cannot be raised. The Congress is to be an American meeting, held in the United States as being the leading American country, and will without doubt be endorsed by the Senators and Representatives in the next Congress as being under government patronage. In such cases, therefore, it seems to us that there is but one city in which the Congress, the first one at least, should be held, and that city is Washington, the capital of America.

CUTANEOUS GEROMORPHISM.

In the *Nouvelle Iconographie de la Salpêtrière*, Drs. Souques and Charcot describe, under the novel title of "Géromorphisme cutané," a unique affection, producing changes in the skin of a young girl which give to her the appearances of old age.

The case first came under the observation of Dr. Laurand in 1881, when the patient was eleven years of age. At that time the changes in the skin, which were already remarkable, were attributed by the parents to a severe fright. The face was most noticeably changed, and suggested a facial paralysis from the obliteration of the natural lines and lack of facial expression. The skin hung in loose folds such as are sometimes seen in extreme age, and appeared as though it had been overstretched from some preceding œdema and had remained too flabby and loose in consequence; but there was no history of œdema having been present. The skin was neither thickened nor indurated, and the condition was plainly not one of elephantiasic enlargement.

Preceding the changes which have been described an eruption had appeared upon the trunk and extremities, lasting for several months, and coming out in crops. The nature of the disease was not made out at the time, but, from the descriptions given, might well have been a form of urticaria. Later on, after the patient had entered the hospital, there occurred another eruption, resembling in appearance and course an erythema nodosum. This rapidly disappeared without apparent influence upon the chronic changes, which had already become well established and had altered the features of an intelligent and pretty child of eleven years into those of an old woman.

No diagnosis was made and no improvement took place. Ten years later, at the age of twenty-one, the patient again entered the hospital and came under the observation of the authors.

Time had only served to intensify the changed appearance of the whole body. There was no evidence of œdema, abnormal pigmentation, or eruption. The skin had simply lost its consistence and elasticity. If lifted up, folded over, twisted, or displaced in any way, the portion of skin thus treated would keep the new position in which it was placed, or return very slowly to its original form, thus resembling the skin of a cadaver. The functional activity of the skin was not interfered with, and the surface was neither dry nor scaly. Perspiration was, however, diminished.

The hair, nails, and teeth were in normal condition There was no pain nor pruritus in the skin, and no evidence of trophic or vaso-motor disturbance. The skin had, in a word, become too large, falling in folds, and becoming wrinkled and furrowed, and abnormally movable upon the subcutaneous planes. The changes are seen to be principally in the dermic, rather than in the epidermic portions; but as to just what has brought about these changes the authors do not feel justified in concluding from their study of the case so far made.

The condition appears to be a special pathological one, without analogy among the recognized dermatoses. Precocious senility is out of the question, as in the latter the hair and teeth are implicated, the digestive functions are impaired, the respiratory acts are diminished, and the muscular system is weakened, which was not at all the case in the instance described.

The parents were found to be healthy, and nothing in the family history pointed to anything analogous, or aided in the solution of what cutaneous geromorphism really is.

News of the Week.

American Electro-therapeutic Association.—The first annual meeting of this Association will be held at Philadelphia, Pa., September 24, 25, and 26, 1891. The following is the programme of the meeting: "President's Address," by Dr. G. Betton Massey, of Philadelphia; "Electro-Therapeutics in America: An Historical Survey," by Dr. A. D. Rockwell, of New York; "The Action and Application of the Faradic Current in Gynecology," by Dr. Augustin H. Goelet, of New York; "Alternative Currents," by Dr. Horatio R. Bigelow, of Philadelphia; "The Treatment of Corneal Opacities by Galvanism," by Dr. C. A. W. Alleman, of Brooklyn, N. Y.; "Report of Seventy-five Cases of Uterine Myomata Treated by Electricity," by Dr. J. H. Kellogg, of Battle Creek, Mich.; "Two Cases of Fibroids where Electricity Ceased to Control Hemorrhage after a Time, although Eminently Satisfactory at First," by Dr. H. E. Hayd, of

Buffalo, N. Y.; "The Treatment of Fibroids by Electricity," by Dr. W. H. Hutchinson, of Providence, R. I.; "Electro-puncture in Uterine Fibroids," by Dr. G. Betton Massey, of Philadelphia; "Electricity in Chronic Parametritis," by Dr. Von Raitz, of New York; "Report of a Case," by Dr. A. H. Buckmaster, of Brooklyn; "Some New Applications of Electro-therapeutics," by Dr. Frederick Peterson, of New York; "The Analgesic Effects of Galvanism," by Dr. Landon Carter Gray, of New York; "Electricity in Diseases of the Stomach, with Exhibition of Patient," by Dr. Lawrence Wolff, of Philadelphia; "Electricity in Carcinoma," by Dr. Robert Newman, of New York; A paper by Dr. W. J. Morton, of New York; A paper by Dr. Henry McClure, of Cromer, England; "Some Points in the Technique of Electrolytic Epilation," by Dr. Plym S. Hayes, of Chicago, Ill.; "A Rare Case of Twin Extra- and Intra-uterine Pregnancy Treated by Electricity," by Dr. G. H. Whitcomb, of Greenwich, N. Y.; "Electricity in the Treatment of Rheumatism," by Dr. W. F. Robinson, of Albany, N. Y.; "The Treatment of Subacute Articular Rheumatism by Electricity," by Dr. M. A. Cleaves, of New York; "Electricity in Anchylosis," by Dr. Von Raitz, of New York; "Has Electricity any Action as a Germicide, or in Producing Poisonous Results in Food," by Dr. W. R. D. Blackwood, of Philadelphia; "Exhibition of a Rectal Electrode, with Remarks on its Application," by Dr. Guy Hinsdale, of Philadelphia; "Abdominal Electro-puncture in an Ovarian Tumor," by Dr. G. Betton Massey, of Philadelphia; "Eight Months' Work in the Dispensary for the Treatment of the Diseases of Women by Electricity," by Dr. H. R. Bigelow, of Philadelphia.

A Medico-legal Institute in Paris.—The municipal authorities of Paris are about to erect a building near the Morgue where all facilities will be provided for the prosecution of medico-legal researches. There will be rooms for post-mortem examinations, chemical and microscopical laboratories, a dark room for photography, an amphitheatre for students, rooms where inquests may be held, etc. All the laboratories now scattered throughout the city will be brought together in one place, so that examinations of suspected cases can be made with much greater ease and despatch.

Body Snatching in Berlin.—A woman died a few days ago at one of the hospitals of Berlin after a capital operation. The case was one of unusual interest, and permission to hold an autopsy was asked for but refused by the husband. So he obtained the body and buried it, but soon after heard that a substitution had been made, the corpse buried by him being that of a stranger, while his wife's body had been retained for the autopsy and afterward buried in Potter's Field. The remains were exhumed and identified, and now the husband has brought suit for heavy damages against the surgeons.

Zeitschrift für Orthopädische Chirurgie.—With the beginning of this year the *Centralblatt für Orthopädische Chirurgie*, edited by Dr. Beely, of Berlin, was discontinued, and a new quarterly journal, the *Zeitschrift für Orthopädische Chirurgie* was established, under the editorial charge of Dr. Alfred Hoffa, of Wurzburg, assisted by a number of the leading orthopedic surgeons of Germany. The English and American editors are Dr. Robert Jones, of Liverpool, and Dr. John Ridlon, of New York, respectively, who furnish reports of the current English and American orthopedic literature. The publisher is Ferdinand Enke, of Stuttgart. The first number, which we have just received, is a royal octavo of one hundred and twenty-two pages, and is in every way a credit to both editor and publisher.

The Apothecary is the name of a new quarterly journal of pharmacy and materia medica, the first number of which is dated in Chicago, August, 1891. It is edited by Mr. Oscar Oldberg, and published by the Illinois College of Pharmacy. It is neatly printed on good paper, and contains, as none who knows the accomplished editor need be told, a large amount of matter of great utility to the pharmacist and student.

A Generous Donation.—For the successful treatment of his wife by a dangerous surgical operation, performed by Dr. Michelsen, of Wiesbaden, Herr von Donner, a merchant of Hamburg, has placed at the disposal of the authorities in Hamburg, as a thank-offering, the sum of two million marks. This money is to be expended in the erection of a hospital in Hamburg, in which Dr. Michelsen is to be installed as chief physician.

Water as a Local Anæsthetic.—Dr. Sleich, of Berlin, states that subcutaneous injections of distilled water will render the part insensible to pain for several minutes, until the wheal caused by the presence of the water has disappeared. He has employed this method to produce local anæsthesia preliminary to the opening of a carbuncle, and was able to incise the parts deeply, and scrape out the diseased portion without any complaint of pain on the part of the patient.

Ambulance Drill in the National Guard.—Some changes have recently been made in the organization of the ambulance corps in the State Militia. For a regiment or battalion the corps will consist of the medical officers of the command, the hospital steward, and as company bearers three enlisted men from each company of seventy-five men, and two enlisted men for each company less than that number. For a troop, battery, or separate company the corps will hereafter consist of the medical officer and four enlisted men. The medical officer in charge of each corps will provide for his men a course consisting of rudimentary instruction in anatomy and physiology, rudimentary instruction in the diagnosis of the nature of accidents and disease manifestations to which National Guardsmen are subject, and the common means for the prevention and treatment of the same; instruction as to the common means employed for the urgent relief of the sick and the injured, including stretcher drill and matters pertaining to transportation of the sick and injured; instruction in individual and camp hygiene.

Dr. William A. Spotswood died in Mobile, Ala., September 7th. He was born in Virginia in 1806. After his graduation as a physician he was appointed in 1829 to the navy, where he served continuously up to 1861, when he resigned to enter the Confederate Army. He served throughout the war as surgeon in Richmond, and at its close retired to Mobile.

Dr. James Ramsey Speer died recently in Pittsburg, in the ninety-fifth year of his age. He was born in Chambersburg, November 19, 1796, and was graduated from Washington College in 1816, being at the time of his death its oldest living graduate. He went to Pittsburg in 1825. He retired from active practice in 1873.

Typhoid Fever is reported to be prevailing to an unusual degree in a part of Wheeling.

Miss Christie, who was graduated recently from the Glasgow University as M.B., was the first woman educated in the Glasgow Medical School.

The Death of a Woman from Methylene was reported not long ago from a small town near Manchester, in England. She was about to undergo an operation for cancer, but died while being anæsthetized.

Dr. J. B. Eggleston, who was graduated this year from the Albany Medical College, was drowned on the night of August 30th, off the coast of Newfoundland. He had been on a trip to Labrador in the steam yacht Albatross, which was wrecked on the reef off Gull Island..

Dr. Joseph Graves Chinn died at his home in Lexington, Ky., on September 7th. He was the oldest physician in Kentucky, having been born on April 1, 1797. He attended lectures at the University of Pennsylvania, and moved to Lexington in 1834. He was married three times, the last time when he was eighty-two years old, and had twelve children and sixty or seventy grandchildren and great-grandchildren.

Vaccinating with Steel Pens is recommended by a French physician. The pens are cheap enough to allow of a fresh one being used for each operation, and thereby all danger of infection from the lancet is avoided.

Dr. Ira D. Strang died at his residence in Ketchum's Corners, N. Y., on Monday, August 31st, aged eighty-one. Up to a few days of his death he had been in excellent health, and able to attend to his professional duties. He leaves a widow and three sons.

The Doctor and the Kaiser.—A correspondent of the *Tribune* says that in view of the connection of Sir Morell Mackenzie with the case of the late Emperor Frederick of Germany, and of the disfavor with which both he and his book were regarded by the present Emperor, there was much curiosity in England to know whether, in the capacity of Chief Surgeon to the Queen's Westminster Volunteers, he would present himself for inspection with that command before Queen Victoria's imperial grandson, a fortnight or so ago. But on the two occasions when he would have been likely to encounter Emperor William Sir Morell absented himself.

American Pediatric Society.—The following is the programme of the third annual meeting of this Society, to be held in Washington, September 22, 23, 24, and 25, 1891:

Tuesday, September 22d.—"Address of the President;" "How to Prevent Complications and Sequelæ in Scarlet Fever," by J. Lewis Smith, M.D., of New York; Discussion on "The Diagnosis of Pneumonia in Infancy and Early Childhood." 1. "The Most Diagnostic Symptoms of the Early Stage of Lobar Pneumonia, and the Differential Diagnosis from such Diseases as Meningitis, Malaria, Scarlet Fever, etc.," by T. S. Latimer, M.D., of Baltimore. 2. "The Diagnosis of Consolidation of the Lung from Effusion (Serous or Purulent), and the Differential Diagnosis between Lobar Pneumonia and Broncho-pneumonia," by F. Forchheimer, M.D., of Cincinnati. 3. "The Diagnosis of Broncho-pneumonia (Acute and Chronic) from Tuberculosis," by William Osler, M.D., of Baltimore. 4. "The Diagnosis of Broncho-pneumonia from Bronchitis, also the Temperature Range in Acute Pneumonia, both Broncho and Lobar," by L. Emmett Holt, M.D., of New York. 5. Remarks by A. Jacobi, M.D., of New York, and by W. P. Northrup, M.D., of New York. 6. General Discussion.

Wednesday, September 23d.—"A Specimen of Congenital Heart Disease," by William Osler, M.D., of Baltimore; "Manifestations of la Grippe in Children," by Charles Warrington Earle, M.D., of Chicago; "The Treatment of Laryngeal Diphtheria by Calomel Sublimations," by Dillon Brown, M.D., of New York; Further Report on "Submembranous Local Treatment in Pharyngeal Diphtheria," by A Seibert, M.D., of New York; "A Case of Ulcerative Catarrhal Dysentery," by W. D. Booker, M.D., of Baltimore; "Stricture of the Œsophagus Occurring in Children, with Report of a Case," by F. E. Waxham, M.D., of Chicago; "A Case of Pulmonary Abscess—Operation and Recovery, with Remarks," by Francis Huber, M.D., New York.

Thursday, September 24th.—"Exhibition of Laryngeal Tubes for the Performance of Forcible Respiration," by J. O'Dwyer, M.D., of New York; "A Study of Fifty Cases of Chorea," by Samuel S. Adams, M.D., of Washington; "A Study of One Hundred and Forty Cases of Heart Disease in Children" (by invitation), by Floyd M. Crandall, M.D., of New York; "Dysentery in a Boy of Eleven Years—Presence of Amœba Coli," by H. Lafleur, M.D., of Baltimore; "Scorbutus in Children," by W. P. Northrup, M.D., of New York; "Chronic Nephritis in Children," by Henry Jackson, M.D., of Boston; "Two Cases of Acute Primary Nephritis in Infants," by L. Emmett Holt, M.D., of New York; "Scarlatinal Nephritis in Children," by J. Lewis Smith, M.D., of New York; "The Application of Gavage in the Treatment of Uncontrollable Vomiting in Infants" (by invitation), by Charles G. Kerley, M.D., of New York; "The Association of Congenital Wry-neck and Facial Herniatrophy," by William Osler, M.D., of Baltimore; "Tubercular Ostitis of the Hip, Originating in Colorado," by John M. Keating, M.D., of Philadelphia; "A Case of Slow Heart in an Infant Terminating in Fatal Syncope," by A. D. Blackader, M.D., of Montreal.

Friday, September 25th.—"The Etiology of Stomatitis Aphthosa," by F. Forchheimer, M.D., of Cincinnati; "Perityphlitis in the Young," by J. Henry Fruitnight, M.D., of New York; "Intussusception," by L. Emmett Holt, M.D., of New York; "A Case of Congenital Cretinism," by C. W. Townsend, M.D., of Boston; "A Further Contribution to Cirrhosis of the Liver in Childhood, with Post-mortem Notes and Microscopic Studies," by W. A. Edwards, M.D., of San Diego, Cal., and W. M. Gray, Microscopist, Army Medical Museum, Washington, D. C.

Dr. James M. Buzzell, one of the oldest physicians in Maine, died in Portland, on September 2d, aged seventy-nine. He was a son of the Rev. John Buzzell, the founder of the Free Will Baptist denomination. He attended lectures at the Bowdoin Medical College, where he was graduated in 1836. He practised for four years at Springfield, Mass., and then went to Philadelphia, where he remained a number of years. He afterward returned to Maine and became active in politics, being an ardent prohibitionist and one of the chief supporters of Neil Dow.

The American Association of Obstetricians and Gynecologists.—The following is the programme of the fourth annual meeting of this Association, to be held in the Hall of the New York Academy of Medicine, on Thursday, Friday, and Saturday, September 17, 18, and 19, 1891: "Address of Welcome and Response," by Drs. Roosa and Rohé; "Post-Partum Hemorrhage: Its Etiology and Treatment," by Dr. Aug. P. Clarke, of Cambridge; "Removal of the Kidney for Disease, with Cases," by Dr. William J. Asdale, of Pittsburg; "Another Method of Palpation of the Kidney," by Dr. Robert T. Morris, of New York; "Intra-uterine Irrigation after Labor," by Dr. Lewis S. McMurtry, of Louisville; "Is a Child Viable at Six and a Half Months?" by Dr. Llewellyn Eliot, of Washington; "Some of the Dangers Incident to Delay in Operating for Uterine Myomata," by Dr. Isaac S. Stone, of Washington; "How Should We Proceed when Abdominal Tumors are Complicated by Pregnancy?" by Dr. James F. W. Ross, of Toronto; "Thoughts Pertaining to Maternal Impressions during Gestation," by Dr. William S. Stewart, of Philadelphia; "Removal of the Uterine Appendages, with Results," by Dr. Milo B. Ward, of Topeka; "A Few Abdominal Sections Selected from my own Work," by Dr. William H. Myers, of Fort Wayne; "The Prevention of Secondary Peritoneal Adhesions by an Aristol Film," by Dr. Robert T. Morris, of New York; "The President's Annual Address," by Dr. Adam H. Wright, of Toronto; "Asepsis in Abdominal and Pelvic Surgery," by Dr. William H. Wathen, of Louisville; "A Case of Cholecystotomy and Cholelithotrity: Death from la Grippe on the Twenty-first Day," by Dr. William Wotkyns Seymour, of Troy; "Report of Cases of Cholecystotomy with Special Reference to the Treatment of Calculus Lodging in the Common Duct," by Dr. A. Vander Veer, of Albany; "Femoral and Ventral Hernia in the Female," by Dr. Henry O. Marcy, of Boston; "Some Moot Points in Ectopic Gestation," by Dr. X. O. Werder, of Pittsburg; "Ectopic Pregnancy: When Shall We Operate?" by Dr. Rufus B. Hall, of Cincinnati; "Trendelenburg's Posture in Gynecology, with Demonstrations," by Dr. Florian Krug, of New York; "Treatment of Minor Lacerations of the Perinæum," by Dr. George R. Shepherd, of Hartford; "Peritonitis," by Dr. Mordecai Price, of Philadelphia; "Peritonitis," by Dr. Edwin Ricketts, of Cincinnati; "Manual Rectification of Certain Malpositions of the Head in Labor," by Dr. William H. Wenning, of Cincinnati; "A Plea for Early Hysterectomy and Puerperal Hysterectomy," by Dr. Joseph Price, of Philadelphia; "Observations on the Surgical Management of Pelvic Abscess," by Dr. Charles A. L. Reed, of Cincinnati; "The Essential Question of Drainage in Pelvic Surgery," by Dr. Lewis S. McMurtry, of Louisville.

American Association of Andrology and Syphilology.—The following is the programme of the fifth annual meeting of this Association, to be held at the Shoreham Hotel, Washington, D. C., September 22, 23, 24, and 25, 1891.

Tuesday, September 22d.—"A Review of the Evidence of the Transmission of Syphilis to the Third Generation," by Dr. Abner Post, of Boston; "Relation of Syphilis to Stricture of the Rectum," by Dr. Robert W. Taylor, of New York; "Observations upon the Syphilitic Cachexia," by Dr. J. Blake White, of New York; "Abortive Treatment of Syphilis," by Dr. J. William White, of Philadelphia; "On the Occurrence of Nephritis in Syphilis." by Dr. John A. Fordyce, of New York; "Exhibition of New Instruments," by Dr. W. K. Otis, of New York.

Wednesday, September 23d.—"A Case of Excision of Stricture and Urethroplasty for Radical Cure," by Dr. Edward L. Keyes, of New York; "A Contribution to the Surgical Treatment of Ruptures of the Bladder." by Dr. Arthur T. Cabot, of Boston; "On the Use of Salicylic Acid in the Treatment of Certain Forms of Cystitis," by Dr. John P. Bryson, of St. Louis; "Undetected Stone," by Dr. William H. Hingston, of Montreal; "Spontaneous Fracture of Stone in the Bladder," by Dr. Francis S. Watson, of Boston; "Note upon a Possible Service to be Expected from Diuretin in Genito-Urinary Surgery," by Dr. Edward L. Keyes, of New York; "Encysted Stone, Complicated with Growths of the Bladder," by Dr. C. H. Mastin, of Mobile; "Treatment of Vesical Calculus in Male Children," by Dr. J. William White, of Philadelphia.

Thursday, September 24th.—"Further Report of a Case of Tubercular Cystitis," by Dr. L. Bolton Bangs, of New York; "Hæmaturia," by Dr. W. K. Otis, of New York; "Clinical Notes on (*a*) Hypertrophy of the Prostatic Sphincter; (*b*) Relation of Rectal Distention to Arterial Depression," by Dr. William T. Belfield, of Chicago; "Notes on the Surgery of the Prostate," by Dr. William N. Wishard, of Indianapolis; "Stricture of the Ureters," by Dr. Francis S. Watson, of Boston; "Observations upon the Surgery of the Ureter," by Dr. Arthur T. Cabot, of Boston; "Exhibition of Complete Double Ureters of Both Kidneys," by Dr. Edmund E. King, of Toronto.

Friday, September 25th.—"On the Radical Cure of Urethral Stricture by Restoration of the Mucous Membrane to a Healthy Condition," by Dr. John P. Bryson, of St. Louis; "An Obscure Case of Chronic Non Specific Urethritis of Sixteen Years' Standing," by Dr. George E. Brewer, of New York; "The Treatment of Urethral Stricture and its Resulting Conditions by Excessive Local Distention and without Cutting—Including a Brief Report of Fifty Cases," by Dr. James P. Tuttle, of New York; "New Methods for the Treatment of Urethral Disease Effected by the Use of the Speculum," by Dr. F. Tilden Brown, of New York; "Treatment of Gonorrhœa," by Dr. W. Frank Glenn, of Nashville; "The Dry Poultice in the Treatment of Epididymitis," by Dr. George E. Brewer, of New York; "Exhibition of an Antiseptic Syringe for Hypodermic Medication," by Dr. J. Blake White, of New York.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Fifty-ninth Annual Meeting, held at Bournemouth, July 28, 29, 30, and 31, 1891.

(From our Special Correspondent.)

SECTION ON SURGERY.

(Continued from page 221.)

SECOND DAY, THURSDAY, JULY 30TH.

Suppuration in the Nasal Cavities.—MR. WALSHAM then considered the question of the diagnosis of suppuration in the cavities connected with the nose. He thought that mucous polypus very seldom caused this. When the discharge escaped posteriorly it was probably from the sphenoidal or ethmoidal sinuses; when anteriorly, from the antrum, the frontal or anterior sphenoidal sinuses. He thought that at present we could not go further in diagnosis than this, although exploratory puncture of the antrum was justifiable and advisable and might settle the diagnosis. As to the situation in which the puncture should be made, he thought only when there was a carious tooth available should extraction and puncture through the alveolus be practised, otherwise it might be done beneath the lip, but such openings were slow to heal. There were difficulties in the way of opening it through the middle meatus. He thought the risks of puncture of the ethmoidal and sphenoidal sinuses too great to justify it, except in the case of dead bone being detected. The only case within his knowledge ended fatally. As to stenosis of the nares he thought that a distinction should be drawn between those cases in which the patient felt and complained of difficulty of breathing, and those where it was first noticed by the surgeon. Only in the former was operative interference justifiable. When deafness was alone complained of, and there was no sense of nasal obstruction, the operation was disappointing in its results. In neurotic cases temporary improvement often occurred, or the symptoms were only transferred to some other organ. Such patients sometimes became insane. He should be very glad to hear what was the experience of others in these aural and neurotic cases.

MR. LENNOX BROWNE commented on the ignorance of nose diseases shown by some surgeons, and remarking on the statistics of the Throat Hospital in Golden Square some twenty-five years ago, said that at that time adenoid growths in the pharynx were not even recognized. Of late years great advances had been made. The use of watery douches, which tended to increase the tumefaction of inflamed mucous membrane, had much diminished, and surgeons tried to employ dry insufflations or oily sprays. The development of intranasal surgery had rendered external operations comparatively rare, although the number of patients who complained of nose troubles had enormously increased.

Nasal Reflexes.—The speaker believed in the reality of nasal reflexes, and thought that Bosworth, of New York, was right in attributing these reflexes to paresis. He thought with this rhinologist that if the nose were treated early it would stop laryngeal trouble or prevent its occurrence. He mentioned a case where local treatment to the nose had relieved aphonia. He had seen cases of recurrent laryngeal growths that were due to adenoid growths of the pharynx, and had known a laryngeal polypus, which accompanied a nasal growth, dwindle and cease to cause symptoms as soon as the nose was cleared out. He believed that laryngismus stridulus in children was almost always due to adenoid growths in the naso-pharynx, and that laryngeal spasm in adults was frequently due to nasal atrophy. A case of so-called glaucoma, for which iridectomy had been recommended and done without relief, recovered when the nose was cleared. Asthma was also sometimes cured by treatment directed to the nasal cavities, but spasmodic asthma was not always due to the condition of the nose even when the nose was affected. Hay asthma could generally be cured by local application of cocaine and chromic acid, and in children sometimes by removal of adenoids. Tinnitus aurium and many other nerve symptoms could be relieved by intranasal treatment. The nose should be always carefully examined in eye disease.

Necrosial Ethmoiditis.— DR. WOAKES considered that Mr. Walsham's paper was too vague, he would, therefore, confine his remarks to a more definite subject, that of necrosial ethmoiditis. This name was first used and the condition first described by himself in a paper read before the Medical Society of London in 1885. The disease was present in most cases of recurrent polypus, and was a rarefying ostitis following on chronic inflammation of the mucous membrane and submucous tissues. Since he had read the paper referred to at the Medical Society some doubts had been cast on the reality of the condition described, and he had therefore submitted all his preparations to Dr. Martin, who reported that he found thickening of the mucous membrane causing pressure on the glands followed by their atrophy. The sinuses were pressed on and the arteries narrowed; on this there often followed absorption and necrosis of the bone. Cysts were often present, but these he looked on as pathological accidents. The fibrosis of the mucosa was the primary lesion. Dr. Woakes handed round many specimens. He said that he thought there could be no doubt as to the reality of the disease. A good light, such as that generally used for laryngoscopic purposes, was needed for diagnosis, and the head should be well thrown back, and the nostril kept open by a speculum. There were various excellent forms of speculum in use, but he preferred Thudichum's to others. It was a cause of great astonishment to him that the condition could be overlooked. The cocaine spray was a most useful preliminary to examination, and a familiar knowledge of the normal appearance of the part was needed to enable the surgeon to recognize the disease. He need only appeal to specimens shown as proof of the existence of the disease, and their pathology was in accord with clinical experience. In the early stages of fibrosis the galvano-cautery was the best application. All drugs except chromic acid were inefficient. Scraping was sometimes of use, but he preferred the cautery. In the later stages the middle spongy bone should be snipped off or removed with the snare, and chromic acid applied to the wound. Sometimes cutting forceps were needed, but any tearing away was dangerous and might produce meningitis or diffuse inflammation of the cheek. Subsequent treatment for twelve months was generally advisable. There was in some cases no alteration in the appearance of the middle spongy bone, yet on probing it would prove to be necrosed.

DR. DONALD STEWART referred to the question of diagnosis of nasal suppuration, which he distinguished from ozæna. There was not in ordinary cases the horrible fetor, evident to the bystander as well as the patient himself, that was so marked a symptom of ozæna. The so-called ozæna was often due to disease in the neighboring cavities, and not to the mucous membrane of the nose itself. These suppurative cases were a great reproach to nasal surgery. The antrum was often the source of suppuration, and could be syringed out through the middle meatus; this was perfectly practicable, and most valuable also as a means of diagnosis. The nostril having been cocainized an Eustachian catheter could be introduced, and if, on syringing, pus escaped, the diagnosis was settled. He believed it possible and practicable to enter the other cavities from the nostril for diagnostic purposes, and looked forward to the time when this would be commonly done.

DR. HILL said that rhinologists in general did not accept Dr. Woakes's statements as to the common occur-

rence of ethmoidal necrosis. He criticised the specimens (some twenty) shown, only two of which he said showed necrosis. He maintained that necrosis was a very rare condition. He did not believe that cystic or swollen middle turbinated bones were of pathological importance, and objected to their removal even when the presence of cyst was diagnosed. He thought they were better left alone. He had succeeded in reaching the frontal sinuses from the nostril.

MR. LENNOX BROWNE did not believe that necrosis was at all common. If it were, why was there no fetor as in ozæna, which was caused by dead bone?

DR. WOAKES in reply maintained the accuracy of his description, and said that the necrosis was often not the death of a large portion of bone *en masse*, but of many small portions.

THE PRESIDENT spoke of the great importance of a thorough examination of the nose, particularly in deaf-mutes. He had in a so-called deaf-mute, by detecting and removing adenoid growths, restored the hearing, and saved him from incarceration in an asylum.

Radical Treatment of Hernia.—MR. STANMORE BISHOP read a paper on the radical cure of hernia. He thought that the predisposing and exciting causes of hernia usually ascribed were not the real ones. It was not in those of weak fibre that hernia generally occurred. He believed that a chronic spasmodic cough was the most important and common cause. He described the operation that he found most effective. Dr. Odell thought the operation for radical cure was seldom curative.

MR STANLEY BOYD had found the operation successful.

MR. WATSON CHEYNE agreed with Mr. Bishop as to the value of operation.

DR. THOMAS H. MANLEY, of New York, had operated at all ages, from five weeks to seventy-three years, with success. He believed that hernia was generally due to congenital predisposing conditions.

Spontaneous Fracture.—MR. HOOKER read notes of a case of spontaneous fracture of the femur in a young man, occurring as he crossed one leg over another to fasten his boot. No constitutional cause could be discovered, but the knee-jerks were absent, although no other evidence of ataxia was observed. He was inclined to think that the severe cold weather at the time might have something to do with it.

MR. A. BOWLBY said that he had seen a similar case in St. Bartholomew's Hospital, and some years afterward the man came under his notice with Charcot's disease.

MR. G. COLIN CAMPBELL then read a paper and showed experiments demonstrating the comparative value of absorbent dressings.

THIRD DAY, FRIDAY, JULY 31ST.

Abdominal Section for Hernia.—MR. LAWSON TAIT opened the discussion on the radical cure of hernia by median abdominal incision.

He referred to the experience of an old medical friend of his who practised in an island off the coast of Scotland far from any other surgeon, and who, he found, had the most supreme contempt for surgical anatomy. His patients were mainly fisher-folk, among whom hernia was common. Yet, although he neglected entirely the six layers described by the anatomists, he had operated in fifty cases without a death. Mr. Tait said that, as a student, so alarmed was he at the difficulties of operation as pictured by his teachers, that he had at the time determined that if ever he should be so unlucky as to have a case of strangulated hernia he would poultice it diligently until he could get some more rashly daring person to operate. He thought that the largely artificial anatomy of the parts taught in the schools was worse than useless. He believed that all the present methods of relief and radical cure were radically false, and that hernia was capable of easy relief and cure by median abdominal section. Removal of the sac was difficult and objectionable, because all opening of the sac when it could be avoided was bad, and left the patient worse off than before. He would propose never to open the sac, and would lay down three principles on which to act: 1. Relief should be afforded without enlarging the aperture. 2. The operation must be simple. 3. The tendinous opening must be closed as well as the sac. He had been led to the subject in connection with ovariotomy. In several cases, when operating on an ovarian tumor, he had seized the opportunity of treating a co-existing rupture, and had afterward operated on hernia uncomplicated by ovarian disease. The old, almost superstitious, dread of opening the peritoneum was no longer to be respected. He thought that with our present methods it was less dangerous to open the peritoneum than to leave it alone in hernia. He found that it was far easier to reduce a rupture from within by pulling than from without by pushing. The diagnosis of hernia was by no means so easy as was generally supposed. He proposed to apply his method to all cases of strangulated hernia, or wherever the radical cure was desired. He had first proposed the operation in a paper published in the *British Medical Journal*, in 1883.

As soon as the finger was within the abdomen the diagnosis was settled. If there were no hernia there was no harm done. If there were hernia it could be cured easily and safely without removing the sac. Operations for incarcerated hernia would be thus much simplified, and incomplete operations, or "reduction *en masse*," would be impossible, while, if an artificial anus were needed, it could be made at the central abdominal incision, which was the best place for it. He described his operation, in which, by the aid of a piece of silkworm gut armed with a needle at each end, he drew the pillars of the ring together, including in the operation the sac. He had hitherto only operated on women, and had had no failures. He thought that the operation would be quite feasible in the male subject, although special provisions would have to be made in inguinal cases for the spermatic cord. Mr. Tait referred to Dr. Maunsell's (of Otago) paper on this subject some year or two ago, and said that his operation was too complicated.

MR. KEETLEY had operated on two cases by median incision. He had had a case where he could not draw back the gut into the abdomen, owing to adhesions between it and the sac, and he was forced to open the sac from the groin. Had almost anyone else but Mr. Tait said that the radical cure was generally possible without operation on the sac he would not have believed him. How was the sac to be got out of the ring in order to allow closure of that orifice? In the inguinal operation it was not always necessary to open the sac; sometimes it could be pushed back into the belly, or twisted, or it could be cut off at the neck. He had given up the abdominal operation for inguinal or femoral hernia. It was a drawback that the surgeon made by his abdominal incision a second potential hernial aperture. He saw no reason to be afraid of touching the sac, and thought that Mr. Tait was superstitious in regard to it. An inexpert operator might do harm in trying to separate the sac from the spermatic cord, and he could not believe that the male canal could be safely closed and yet leave room for the cord. He hoped, however, to be converted by what he should hear to-day. Hernia cases were so diverse that it was difficult and dangerous to generalize. He thought that when special reasons existed for leaving the sac alone, Tait's operation would be valuable.

MR. JORDAN LLOYD had not performed the abdominal operation, but had seen two cases in which it was discovered that the gut could not be withdrawn. Modern herniotomy with radical cure was a most simple and successful operation. The great desideratum was to get patients to submit to operation earlier. In one hundred cases he had seen none in which Tait's operation would have been preferable. Surgical anatomy was at least of some use. He believed that the gut could not be withdrawn in many

cases without division of tendinous structures when the hernia was strangulated, and it was in those cases that the question was most important. There would, he thought, be danger in returning the sac and allowing the fluid which it often contained to reach the general peritoneal cavity. The difficulties in the operation for radical cure were due to the operator's deficiencies. All cases that could properly be dealt with by median abdominal incision alone could be treated by non-cutting means.

Mr. Gilbert Barling said that most of Mr. Tait's cases were not strangulated. These were simple and easy. He shared Mr. Jordan Lloyd's objections in strangulation cases. Tait's operation was useful in umbilical and obturator hernia. He agreed with Mr. Keetley as to the risk of producing a ventral hernia at the scar, for the predisposing causes, anatomical or otherwise, of hernia still existed in the patient. If the gut were damaged or gangrenous it could not be inspected without risk of extravasation. He thought that in femoral hernia there would be risk of wounding vessels with the needles.

Mr. Greig Smith had come with open, and even sympathetic, mind. He objected to the division of tendinous structures which did not recover their former condition, as shown by the fact that the worst herniæ were those following operations for strangulation. The time occupied was important. Herniotomy only occupied five minutes, but who but Mr. Lawson Tait would do an abdominal section in that time. It was unsafe to work at herniæ in the dark, as must be done in operating from within.

Mr. Bennett May thought Mr. Lawson Tait had underrated the nature of modern herniotomy and its success. Adhesions were a great objection, and it was not so easy to divide the stricture from within as from without. The operation generally practised left nothing to be desired.

Dr. Maunsell said that his paper referred to was published five years ago and was on supra pubic laparotomy. He recapitulated the advantages of the method, and said that the constriction in strangulated hernia was at the neck of the sac, and not at the tendinous ring. The operation need only take three or four minutes. The entrance to the crural canal could not be closed from without, but it could be from within. He did not advocate laparotomy in inguinal hernia, but in all other forms. It was never necessary to use the knife to relieve constriction in femoral hernia. He pulled up the resisting ring with a button-hook. Mr. Tait had said that his operation of radical cure was difficult and complicated, but, as he would show by a diagram, it was essentially the same as Mr. Tait's.

Dr. O'Callaghan thought experience would limit this operation to umbilical hernia. He thought it impracticable in many cases of femoral and inguinal rupture.

Mr. Stanley Boyd concurred with what Mr. Greig Smith had said. He was quite satisfied with the results of radical cure operations from the groin.

Mr. Stanmore Bishop asked, whether we were to decide between the two methods was not each advisable in suitable cases? He thought that there was no more harm in having two wounds than one.

Dr. Thomas H. Manley said that coming from such an authority the method deserved serious consideration. It was most useful in women having abdominal tumors, but not generally applicable. It was inconceivable to him that an experienced surgeon should recommend this operation for a bad strangulated hernia with fluid in the sac and possible gangrene of the gut.

The President said they were all much indebted to Mr. Lawson Tait. He would like to know how many cases of strangulated hernia he had operated on.

Mr. Lawson Tait in reply said that he now saw by Dr. Maunsell's diagram that the two operations were practically the same. Dr. Maunsell, however, could not have published his paper five years ago, as the first operation was stated to have been in March 1887. He was astonished to hear Dr. Manley speak of operating in the linea alba, as he had for years been preaching that it should be avoided. He did not propose to substitute this operation for the inguinal one. From the nature of his practice he had not had many strangulated cases.

Fissure of the Anus.—Dr. C. B. Ball then read a paper on the "Pathology of Fissured Anus." He said that true fissure was in his opinion due to the tearing down by a hard motion of one of the anal valves. He likened this to a hangnail, and said that the pile which so often existed at the end of the fissure was really the torn-down valve. Removal of the so called pile was all that was needed. He adduced the record of ten cases in support of his theory.

Dr. Maunsell said that there was often no pile visible, yet dilatation cured it. How was this? Similarly, cases were cured by a free division backward of the sphincter. He had never known a case that division of the sphincter and dilatation would not cure.

Dr. Ball said that in dilatation the tag of skin was pulled down. He thought that if Dr. Maunsell looked more carefully at his next case he would find the pile.

Hot Water in Surgery.—Dr. O'Callaghan then read a paper on hot water flushing applied to general surgery. He said that five years ago he had abandoned Listerism for hot water and cleanliness, and had not regretted it. It must be thorough and copious, and at the temperature of 112° F.

The President warmly commended the practice of hot flushing, without which, he said, no operation was safe.

Gastro-enterostomy.—Dr. C. Renton then read a paper on a case of gastro-enterostomy for pyloric tumor. The nature of the growth, which was suspected to be malignant, was not determined, and it was left *in situ*. The patient made a good recovery in three weeks, and now, eight months afterward, was well and had gained flesh. He used Senn's decalcified bone-plates.

Dr. Maunsell spoke of the difficulty and time occupied in inserting the supplementary sutures in such cases.

MEDICAL SECTION.

First Day, Wednesday, July 29th.

Etiology and Prevention of Phthisis.—Dr. Pye-Smith, the President of the Section, opened the debate on this subject. He defined phthisis as a chronic disease, always tubercular, with great capacity for healing. The microbe was present in the disease in all cases. The coincidence of the bacillus with phthisis was clearly proved. It did not follow, however, that phthisis was a contagious disease. It was about as hard for an old man to get typhoid fever as to learn a new language. Hence there must be predisposition. Otherwise, why did not all persons attending consumption hospitals, or living in hotels where many consumptives congregated, get the disease?

Dr. Blake read a paper on cancer and phthisis occurring in the same family. In 1860 he had to attend a patient with phthisis, and in this family there were several cases of cancer. A daughter of this woman died of cancer; a son of consumption. He held that his cases showed that cancer and consumption might be transmitted from husband or wife to the healthy partner.

Cure of Phthisis.—Dr. Burney Yeo observed that it was undoubtedly true that phthisis was occasionally cured. Some patients had no clinical symptoms, and might be described as consumptives who had no phthisis. It had been said that it was very difficult to cure tuberculosis which had reached the stage of phthisis. It was of great importance to ascertain the existence of the disease in the pre-phthisical stage. He held that even if cure of certain cases could be obtained, there were many cases which were hopeless. Brouardel and others had asserted that there were many cases where tuberculosis

had affected the lungs without producing phthisis. The diagnosis of the pre-phthisical period was extremely important. Jerky inspirations, with anæmia, and early hæmoptysis were symptoms of this stage of the disease.

Dr. W. Walker had gathered that the words phthisis and consumption were considered to be synonymous. He looked on phthisis as a general tuberculous disease. Was the phthisis of stone-masons or quarrymen tubercular? He thought not, and had seen many such cases in the locality where he practised, in the neighborhood of the city of Glasgow. He thought that a discussion should take place as to the future signification of the words phthisis and pulmonary consumption.

Sir Risdon Bennett confessed that his own opinion was undecided on many of the points which had been touched upon. Admitting that in phthisis the bacillus was present in most cases, he asked whether the bacillus was equally readily found in tuberculosis of the perito neum and brain. Was the bacillus found in children's tuberculosis? He was convinced that it was extremely important to investigate the disease in organs besides the lungs to ascertain these points.

Dr. Sansom had made an analysis of twenty cases of arrested phthisis. He thought this would not bear out the idea that the pre-tubercular stage was the only one curable. Why were children immune from phthisis pulmonalis in some cases under twelve months? Tuberculosis certainly occurred in such infants, but ordinary tubercular phthisis did not often occur in them. Phthisis was very uncommon in cardiac diseases. It was almost never seen. He had never seen phthisis with mitral regurgitation, but he had seen it in mitral stenosis. It was rare in all cardiac diseases. The probable cause of this was that there was hyperæmia in the lung, which prevented the flourishing of the tubercle bacilli. In stenosis of the pulmonary artery the patient very frequently died of phthisis. For the production of phthisis the bacillus was not the only factor. There must be a predisposing circumstance.

Dr. Moorhead said that on the Continent one-fifth of all deaths were due to phthisis. About twenty five to thirty per cent. of cases were hereditary. He alluded to Dr. MacCormac's views as to pre-breathed air. Where the population was sparse there was but little phthisis. As to prevention, the avoidance of over-crowding was the most important point. Good animal diet was useful. The carnivora were rarely affected. He saw no reason why phthisis might not become as rare as leprosy had become in this country, for if it was so rare in country districts and in sparse populations, it was evidently highly preventable.

Dr. Morgan thought that in many cases of phthisis there must be a lower vitality brought about by sedentary work. There was a want of expansion of the lungs in many cases, which predisposed the patient to attacks of the germs which caused it.

Dr. Handford said that something in addition to the bacilli was requisite for the production of the disease. One of the conditions was low blood tension; in certain forms of heart disease there was almost complete exemption from tuberculosis. Possibly this might account for the tuberculosis of children, who had low tension of the blood. There was some connection between menorrhagia and phthisis. He thought that this disease was often followed by phthisis, because it gave rise to lower vascular tension. Vegetable feeders were predisposed to tuberculosis, whereas among the carnivora it was almost unknown; a dislike to meat diet was often met with among patients with phthisis. Meat diet raised the vascular tension. A large amount of fat, too, was probably taken by vegetarians.

Dr. C. R. Drysdale said that ever since 1865, when he had in Paris listened to the views of Dr. Villemin on the inoculability of tubercle, he had become convinced that tuberculosis was a virulent disease, and that it was most like syphilis and leprosy in its pathology. He believed that, like syphilis, phthisis was derived from parents, and that it was not merely the predisposition to the disease that was inherited, but the disease itself, which did not appear for some years in the lungs, but often came in the form of joint disease and other forms of scrofulous affections. He related a number of cases in which he believed that the disease had been derived from contagion. One was that of an elderly medical man, aged seventy, who nursed most tenderly an only daughter affected with chronic phthisis. After her death he was seized with acute tuberculosis and rapidly succumbed. He believed that many cases of "hereditary" consumption were caused by contagion between children in the same family inhabiting infected apartments.

Dr. Bristowe said that he was a convert to the bacillary theory of phthisis. And he therefore was compelled to assent to the proposition that the disease must be contagious. The specific cause of phthisis lay in the presence of the bacillus; but in addition to this factor in its production, there must be provided a proper soil for the existence of this parasite. The germs of phthisis existed in a great variety of places frequented by mankind. The chief point in prophylaxis that physicians had to look to, was the preparation of the patient to enable him to resist the invasion of the bacillus.

Dr. Thorowgood said, with regard to the origin of phthisis, that some patients had exhibited great terror, and this might sometimes account for deaths in the same family. He spoke of "pulmonary cachexia" occurring in seamen sleeping in very foul air. The importance of getting rid of inflammatory products was insisted upon. Dr. Rush used to use mercury in such cases. Hypophosphite of soda was useful in getting rid of inflammatory products. Dr. C. J. B. Williams had said that hypophosphite of soda gave the power of assimilating oxygen.

Dr. Dale has never seen any case of consumption conveyed from one person to another. As to inheritance, he had a firm belief in the predisposition from hereditary transmission. He cited the case of a family where several daughters came home affected with the disease. All the cases died. The inheritance came through the father's sisters. In a great number of cases we must have bad air also to produce the disease.

Dr. Solomon Smith said that if we believed in the experimental pathology of the disease, we must admit that phthisis was contagious. But there must be something far more than this. Tubercle fell largely under the care of surgeons, and this disease often arose from injuries to the joints. In the same way phthisis pulmonalis was often due to a damaged lung. Phthisis grows best in an injured lung. There was a certain vitality inherent in different people which protected them.

Dr. Bookhurst was not convinced of the bacillary causation of phthisis, and he was glad to find that Sir R. Bennett was doubtful as to this point. Koch's process had done far more harm than good. The speaker thought that hæmoptysis was sometimes the cause of phthisis.

Dr. Humphreys said it had been assumed that animal feeders were more subject to phthisis than vegetable feeders. He had been a vegetarian for some years. He admitted that beans were nitrogenous and that nuts were oily, yet he could speak very favorably of his vegetarian experiment.

A member said that common catarrh often led to phthisis in his experience, and that great care should be taken to see that patients were thoroughly cured of such catarrhs before they abandoned treatment and recommenced routine work.

Second Day, Thursday, July 30th.

A Discussion on Lupus was opened by Dr. I. F. Payne. The only difficulty in the causation of lupus was whether it was or was not connected with tuberculosis. He left out of consideration lupus erythematosus. The

cause of nearly all growths of chronic character was now recognized to be parasitic. In the case of syphilis, although no one had seen the microbe, yet all recognized that it was due to a micro-organism. It has been said that lupus tissues contained the bacillus of tuberculosis. The arguments in favor of this were that there were giant-cells in lupus, as there were in tuberculosis. In a great number of cases the bacillus of tuberculosis had been noticed.

Koch had repeatedly produced tuberculosis in rodents by inoculating them with lupus. This was certainly an important test. Lupus began in a slow and persistent manner, going on for years. In this it resembled tuberculosis. Lupus was very rare in infancy and in old age. In this, too, it resembled tuberculosis. As to statistics, the minority of lupus patients had had tuberculosis. It was certainly common in tubercular families, and was occasionally itself transmitted in its own form. There could be no clear line drawn between scrofuloderma and lupus. Scrofuloderma and lupus were probably produced from the same tubercle bacillus. The way in which the bacillus obtained admission was the difficulty. It was seldom that lupus began with a wound. If this were so, it must be brought by the blood. In some cases there was multiple lupus; but that was rare. Why did lupus not run the same course as tuberculosis of internal organs? The temperature of the skin was only about 80° F. Internal tubercle produced fever, which promoted the growth of the bacilli. This might account for the modification of its growth in the skin. The general treatment and the local treatment of lupus were the same as those of tuberculosis.

Dr. Pye-Smith thanked Dr. Payne for his address. With regard to inoculations, were there any proofs that such inoculations were successful when the bacillus was absent? Hebra had asserted that lupus was only met with in early life. Sometimes few or no bacilli could be seen in lupus, which was curious as compared with the numbers seen in phthisis. With regard to statistics, it must be remembered that phthisis was a very common disease, and hence, in the case of statistics of lupus, this must be borne in mind. There was a real distinction between scrofuloderma and lupus.

Dr. Colcott Fox was glad that there was a public debate on this subject. There was no doubt that giant-cells were not absolutely necessary in tubercle. Several observers had alleged that lupus was tubercular before the bacilli were known to exist. The bacilli were certainly infrequent in lupus; but, if sufficient trouble were taken, it was quite exceptional not to find them. The skin was a very bad place for the bacillus to grow. There had been a certain number of hereditary cases of lupus. A great number of cases of lupus commenced in the first ten years of life. He had seen seven cases in the first twelve months of life. These ages coincided with other tubercular diseases in children. Other tuberculous diseases were certainly often co-existent with lupus in children. He held that there could be no clear division between scrofuloderma and lupus.

Dr. Abraham said that he had examined fifteen cases of lupus, and had not found the bacillus tuberculosis, although he had always seen it in phthisis. He had seen lupus in old patients and also in very young patients. He had had 21 cases under treatment, 3 of which had been cured, and in 12 great improvement had taken place. There had been no improvement in 2 cases. Some of the patients had been scraped, and 3 had been almost cured. Salicylic acid and resorcin were used. In hyperæmic cases tuberculin was useful. He believed that lupus was a form of tuberculosis.

Dr. Moorhead thought that all agreed with Koch in his views as to the causation of lupus by irritation from the bacillus tuberculosis. He mentioned that in the case of a lady with lupus, Sir James Paget had recommended a saturated solution of caustic potash as a local application. This was followed by cicatrization. She took a wineglassful of cod-liver oil thrice daily, and was quite cured of her lupus.

Dr. Radcliffe Crocker thought that lupus was a bacillary disease. He agreed with Dr. Pye-Smith that there was a great difference between scrofuloderma and lupus. Lupus might occur at all ages from infancy to old age. With regard to treatment, he believed that Koch's tuberculin had some curative, and a good deal of palliative, effect. His plan was to get rid of a good deal of the tissues with the spoon and then to inject resorcin, and he had found this a very curative treatment.

Dr. F. Augustus Cox remarked that, with regard to the connection of lupus with tubercle, the fact that tubercle bacilli could not be found in some cases of lupus was an argument against the tubercular nature of lupus. He agreed with some of the previous speakers, that scrofuloderma was distinctly marked off from ordinary lupus, and especially by the effects of general treatment, such as by iodides, cod-liver oil, and sea-air. Internal treatment was not of much service in cases of ordinary lupus, though he had seen some benefit result from small doses of arsenic in chronic cases. Were he himself the subject of lupus, he would prefer not to employ Koch's treatment, but to rely on free scraping followed by the application of resorcin, from which he obtained excellent results.

Mr. Gilbert Barling said he had carefully examined twenty cases, and in half of them he had found bacilli and in half none. In only one case had he found tubercle bacilli in large numbers; but this was in a patient also afflicted with phthisis. In two inoculations, made one on a rabbit and the other on a guinea-pig, in the first case lupus was produced, and in the other generalized tuberculosis. He considered that the reason why tubercle bacilli attacked the face was because that part was most exposed. The vascularity of the face was so great that it favored inoculation more than other parts. He had seen lupus arise around a sinus from bone disease. In twenty to twenty-five per cent. of lupus cases some other tubercular lesion would be found. He did not accept the congenital origin of lupus or tuberculosis. He thought that milk was a cause of early tuberculosis in many cases.

Mr. Startin thought that lupus erythematosus was the pure form of lupus. He had seen some cases of hereditary transmission, and had seen some cases of lupus erythematosus caused by cold.

Mr. Clement Lucas mentioned the case of a policeman who had struck a man, and lupus spread from his knuckle over the back of the hand.

Dr. Payne, in closing the discussion, said that in scrofuloderma the disease was deeper than it was in lupus.

The Use of Drugs in the Treatment of Early Phthisis.—Dr. Thorowgood read a paper on this subject, in which he spoke with great praise of the hypophosphites. He mentioned the case of a medical man who had quite recovered his health from the administration of hypophosphite of soda. Two grains of the salt, given twice or thrice daily, were sufficient in many cases to effect a cure. In cases of pleurisy with effusion there had been no good effect. Another gentleman ate meat thrice daily and recovered. The hypophosphite of potash was too active a drug to be safely used. The hypophosphite of lime was sometimes also of great use. He had used iodide of potassium and mercury, but rarely with any advantage. One case had been completely cured by a voyage to Australia. At the Victoria Park Hospital inhalations had proved very useful. Some patients slept with creasote inhalers, and were much benefited. Severe counter-irritation was occasionally extremely useful. Croton-oil liniment was excellent. Liniment of turpentine and acetic acid was useful, used until the skin became sore.

Helenine in Tuberculosis.—Mr. Bokenham had found that the use of the crystals of the substance, given in solutions of 1 in 10,000, prevented the growth of the tubercle bacillus. He then administered helenine in the form of pills or tablets to guinea-pigs; no ill effect was produced on the animals. The animals, when inoculated by tuber-

culosis, died after about one hundred days. Control animals died in about a month or so. It was easy to render the tubercle bacillus so non virulent that inoculation with it produced only local affections. Dr. Vincent Harris had used the drug at the Victoria Park Hospital, but he had used very small doses. He had given it in suitable doses thrice daily in some cases in his own practice, but had not had any clear results as yet.

Dr. Blake had used the tar spray in the form of creoline. He believed in the treatment of phthisis by dry air.

Dr. Thorowgood said that the hypophosphites were of great use in his experience, and he cited the opinion of a former pupil at the Victoria Park Hospital, now medical officer of the Marylebone Infirmary, as corroboration of this view. Another of his pupils had, however, expressed his want of faith in the efficacy of the drug, and some friends had suggested that he would find carbonate of soda quite as useful; but he advised such sceptics to make a careful trial of the drug, and believed that they would change their views.

Sudden Deaths in London.—Dr. Wynn Westcott read a paper on this subject in which it was shown that of one thousand deaths on which inquests were held, twenty-nine per cent. were caused by alcoholic excess.

A member said that he had not gathered from Dr. Westcott's cases whether the alcoholism which caused death had been chronic or acute. Failure of cardiac walls had in his experience been the main cause of sudden death. A gentleman, aged forty-seven, had never been drunk, but died suddenly from cardiac syncope from chronic alcoholism.

Dr. Norman Kerr pointed out the importance of the statistics cited by Dr. Wynn Westcott. He had long recognized that the chief danger to life from alcohol lay in daily moderate doses of alcoholic fluids. He would be far less afraid of the sudden death of a man who got drunk once a month, than of one who daily partook of a fair amount of alcohol without ever exceeding what he thought the bounds of moderation.

Dr. C. R. Drysdale thought that after the discussion of the etiology of tuberculosis that of the causation of death by alcohol was the most important topic which could be brought under the notice of the Medical Section. Mr. Wackley, coroner for Middlesex, had once told him that in nearly one-half of the inquests held on adults in his district, death was due to alcoholic excess.

Third Day, Friday, July 31st.

Galvanism in Intestinal Obstruction.—Dr. Semmola, of Naples, read a paper on "Intestinal Obstruction Successfully Treated by Galvanism." A patient had purulent diarrhœa, for which he was treated by purgatives. There was complete occlusion and great suffering. There was suppression of urine, which suggested to Dr. Semmola a nervous affection. Accordingly he recommended the constant current. The negative pole was applied with sponges externally. Ten-minute sittings were given every eight hours. In the twelfth application the intestinal obstruction ceased. The President summed up the case in English, and mentioned that Sir Thomas Watson had advised this treatment in intestinal obstruction.

The Effects of Alcohol.—Dr. Wilks said that it was quite impossible to divide the therapeutical from the dietetic use of alcohol. It would be easy to advise complete disuse of alcohol, and also it would be easy to say that the temperate use of wine was of importance to the race; but it would be difficult to deny that the universal use of a substance was an indication that it was suited to the race. The effect on the nervous system was the predominant effect. In excess it caused paralysis. It was not clear that there was any connection between alcohol and kidney disease. It was not clear what became of the alcohol taken into the body. Some said that it is a food of the lungs. No one had as yet seen a person live on alcohol; but it had been often remarked that people could live on very little food if alcohol were added. Persons in good health did not require alcohol. Children were better without it; but in old age and in anxiety it would be found useful. In the middle classes the beer-drinker was usually a temperate man. In some cases wine was a sedative. Many of our ancestors lived to a great age and drank a great deal of wine, and the speaker thought it was a pity to apply the term poison, as some total abstainers did, to a substance so much used by all classes. There was scarcely any nation that did not use alcohol in some form, and it would be quixotic to try to get rid of alcohol. If this were attempted it would be necessary to combat smoking and tea, etc. If a temperance hospital had existed in Todd's day it would have been of use. A large number of persons used to give brandy to all sick persons. He wished much to know what were the cases in which alcohol should be given. In one case, in a boy, doses of brandy had taken down the pulse and lowered the temperature. In many cases of fever, alcohol did not produce inebriety. An injection of wine into the rectum had apparently saved the life in a case of post-partum flooding. In wasting, or atrophy, of children he had found alcohol extremely useful. In extreme emaciation he once ordered a drachm of spirits of wine thrice daily, and the child put on flesh.

Dr. Ridge pointed out the effect of alcohol on the nervous system. The use of alcohol affected the vasomotors, and the brain received a larger supply. The higher centres were damaged, and first of all, the flow of language was greatly affected. Small quantities used daily were apt to produce dangerous effects. He showed poppy seeds and other plants (geraniums) which had been damaged by the use of small quantities of alcohol. Alcohol promoted the growth of the bacilli in a hay infusion. The reason why people took alcohol was because it was a matter of fashion to do so. Put wine into the pharmacopœia, he said, and use it only like ether or arsenic.

Sir Risdon Bennett thought a distinction must be made between the use of alcohol in health and in disease; there were many who got through their work better with than without wine. He rarely took any of the stronger wines with his meals, but made it a point to take two glasses daily of port wine. When he was abroad he took claret or champagne. Any excess of wine would not make him foolish, it would only make him stupid and silent. He could not make rules for the world at large. As a rule he agreed with Dr. Wilks, and did not think it useful to call alcohol a poison, as some did. That was not the way to win people to total abstinence.

The question was discussed at length by Drs. Bucknill, Norman Kerr, Semmola, Drysdale, and others, and then the Section adjourned.

The St. Louis Miracle.—Dr. Alt, of St. Louis, has been widely quoted as testifying to the truth of the facts put forth in regard to the alleged miracle in a convent in that city. Dr. Alt writes as follows, in the *American Journal of Ophthalmology*, concerning his connection with the case: "On April 4th last I was called by a letter of the Mother Superior to see a Sister who was said to be suffering greatly. When I saw the patient I was told that she had on that day bled profusely from the left eye without provocation. I found a red upper eyelid, as if it had been rubbed, and a slight photophobia, but nothing else. I told the Mother that I could not find anything for which my services might be of any use. According to the Sister's story, I presumed that she was afflicted with hæmophilia, as she was stated to have bled from different parts at slight provocation or without it. This is all I know of the miracle case. I saw the Sister only that once. I did not do anything for her. I had nothing to do with the subsequent alleged miracle, and could, therefore, not vouch for it, even if I believed it."

THE CONGRESS OF HYGIENE — THE VALUE OF THE WORK DONE — THE BRITISH PHARMACEUTICAL CONFERENCE — THE EASTERN FEVER HOSPITAL SCANDAL.

London, August 26, 1891.

Now that the Congress of Hygiene is over, people are beginning to discuss the value of the work done. In many respects the Congress has been an undoubted success. It has brought together a large number of *savants* from different countries and enabled them to interchange ideas face to face on a variety of subjects. Personal intercourse does much to vivify interest, and in this respect the Congress has undoubtedly done good. When, however, we come to appraise the direct scientific value of the papers read and of the discussions held we come upon grounds where we meet with diverse opinions. While some consider the Congress to have been of great value to hygienic science, others stigmatize it as valueless. I cannot agree with the latter opinion, though at the same time it is not difficult to see that the contributions to the Congress were of very unequal value.

Among the subjects of interest brought forward and not noted in the Special Report already sent you, I may mention a discussion on "Vertical Writing," in Section IV. It was urged that this should be taught in schools as the sloping hand ordinarily taught tended to produce bodily deformity in the scholars, who contorted their bodies to produce the sloping hand. A resolution in favor of vertical writing was ultimately carried. In the Section of Preventive Medicine Dr. Arthur Ransome read a paper on "The Prevention of Consumption," in which he urged that the disease was both curable and preventable. Its curability was proved by (1) finding old healed phthisical lesions in the bodies of persons dying from other causes, (2) the testimony of eminent physicians, (3) the returns from consumption hospitals. Its preventability was proved by the diminished mortality from the disease which had followed the drainage and ventilation of barracks and of towns. Dr. Edward Squire and Dr. Gilbert (Havre) also read papers on the same subject. Greene Pasha read a paper on "The Influence of the Nile on Mortality in Egypt," in which he showed that in nearly all the towns of Lower Egypt the mortality rose as the river fell and became stagnant. Pure water, drainage, and ventilation were required to bring down the enormous mortality. Pure water could be provided if money were available. Dr. Van Dooremal (The Hague) read a paper on the "Prevention of Blindness Due to Occupation." In rural districts, he said, it was generally caused by an insignificant lesion followed by infection; in towns, a severe traumatism was the usual cause. Much could be done to protect work-people. Dr. Phineas S. Abraham read a paper on "The Alleged Connection of Vaccination with Leprosy," in which he expressed the opinion that vaccination was not to any extent responsible for the spread of the disease. It nevertheless behooved medical men to be extremely careful in the selection of their lymph for vaccination, and in a country where leprosy was rife it would be advisable to exercise special caution, and, if possible, avoid (as was now done in Hawaii) an indiscriminate arm-to-arm vaccination among the natives. In Section V. Professor Lehmann read a paper on "The Hygienic Importance of Copper," in which he urged that the admixture of even small quantities of copper salts with food should be guarded against. Dr. Garrett read a paper on "The Action of Water on Lead." He maintained that oxidation took place — a white, crystalline, insoluble, oxyhydrate of lead being formed. Dr. Percy Frankland discussed the "Importance of Magnesia in Drinking-Water," and Dr. Bahadwidji (Bombay) read a paper on "Air Analysis," in which he dwelt upon the injurious action of re-breathed air. A paper by Dr. Marcet, on "The Effects of the Respiration of Carbonic Acid on Man," was read. The practical conclusions drawn by Dr. Marcet were that people working in badly ventilated rooms should sleep in as pure an atmosphere as possible, so as to get rid of the carbonic acid absorbed by the blood during the day; that the effects produced by inhaling the gas depended greatly on the rapidity of the exposure; that when life was threatened by the inhalation of carbonic acid there was no reason to despair of artificial respiration so long as the heart was beating.

A somewhat amusing incident occurred on the last day in Section V., when the President of the Section (Sir Henry Roscoe) proposed to rescind the motion as to the disposal of sewage which had been proposed by himself and carried at a previous sitting of the Section; the ground for this procedure was that the motion which had been passed contravened a rule of the Congress which prohibited the taking a vote on purely scientific questions. In Section VI. a little jealousy was evinced at the closing meeting in regard to a motion which had been carried in Section IX., and a resolution was adopted expressing the opinion that the resolution which had been carried in Section IX. as to the statutory examination and registration of architects should have been referred to Section VI., and that the motion should be considered by the Congress before it was finally adopted.

During the past week the British Association for the Advancement of Science, the British Dental Association, and the British Pharmaceutical Conference have been holding their annual gatherings. Mr. Martindale presided at the British Pharmaceutical Conference and claimed that pharmacists should occupy a higher position. In the investigation of disease, he said, therapeutists and pharmacists had come between the physiologists on the one hand, and chemists and botanists on the other. Generally chemists had been in advance of physiologists, but the latter had at times, by a process of induction, indicated the direction in which chemists should work.

The Metropolitan Asylums Board is again in hot water. At a meeting held on Saturday last the report of the Local Government Board on the recent scandals at the Eastern Fever Hospital was read. The Local Government Board expressed the opinion that the interests of the hospital left them no alternative but to require the resignation of the Medical Superintendent, Dr. Collie. They found that the food had been improper, the arrangements for disinfection unsatisfactory, and that music and dancing had been kept up to a late hour in a fever ward.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE TUBERCULOSIS CONGRESS — OPENING SESSION — NON-IDENTITY OF GALLINACEOUS AND HUMAN TUBERCULOSIS — DOGS AND GOATS NOT IMMUNE — LANNELONGUE'S CHLORIDE OF ZINC METHOD.

Paris, August 15, 1891.

The second Congress for the Study of Tuberculosis, whose sessions have recently been brought to a successful termination, is regarded here as an event of great importance, and it is hoped that beneficial results in the line of prophylaxis and therapy will flow from it. A report of the proceedings has already been sent you, but there are some points of interest that may not have received the emphasis they deserve, or even if they have, will perhaps bear repetition.

The Congress (for whose existence we have to thank Professor Verneuil and Dr. L. H. Petit, Librarian of the Faculty) was inaugurated on the 27th ult. in the grand amphitheatre of the Faculty of Medicine, under the presidency of the veteran Villemin, to whom is due the credit of having, as long ago as 1865, proved experimentally the

infectious nature and the inoculability of tuberculosis. About four hundred native and foreign physicians and veterinary surgeons assembled to listen to addresses delivered by the President, and by Professors Verneuil, Grancher, and Arloing.

One of the more important discussions of the Congress was concerning the identity or non-identity of the different forms of tuberculosis, as seen in man and the lower animals. The opinion which has been formulated was here generally accepted, namely, that the bacilli present in gallinaceous and human tuberculosis constitute specimens of two distinct races, while the bovine and human micro-organisms are identical. It has also now been demonstrated that the hitherto accepted belief in the immunity from tuberculous infection enjoyed by the dog and goat is unfounded. M. Chantemesse, in effect, cited an instance of spontaneous tuberculosis in the dog. To this observation we may add that of M. Bernheim, who related that a dog which had had the run of the hospital yard in the pre Listerian epoch (in France), and was in the habit of devouring garbage, the expectoration of phthisical patients included, died after an illness of six months' duration, of well-marked pulmonary consumption. Another example of canine tuberculosis is due to M. Beucler, a veterinary surgeon, to whose care was confided a dog, aged three and one-half years, presenting all the symptoms of phthisis pulmonalis. The animal died recently, and the necropsy revealed a "shower" of young granulations scattered over the pleura and pericardium, together with more ancient lesions (infiltration and cavities) in both lungs, bacilli being discovered microscopically. As regards the goat, M. Colin, of the Veterinary School of Alfort, having inoculated that animal in the flank with a minute fragment of cow's tubercle (pulmonary), was able to observe the gradual development at the seat of inoculation of a tubercular growth, with enlargement of the corresponding precrural lymphatic glands. Having undergone caseous degeneration, the tumor broke down, and the animal being killed, the autopsy brought to light enlargement of a chain of glands extending through the pelvic, lumbar, dorsal, prescapular (corresponding to the axillary glands in man), and mediastinal regions, the adenopathy being strictly limited to the side corresponding to the inoculatory puncture. The lung contained no less than one kilogramme of tuberculous growth. Not a trace of infection was discovered in the intestine, liver, or other organs. The hopes founded upon the assumed refractoriness of the dog and goat to the bacillus, that the serum of these animals introduced into the human system would act as an antidote to the micro-organism or the toxines excreted by it, are thus, by the demolition of the theory upon which the treatment reposed, considerably diminished. M. Beucler, moreover, pointed out that, as rabies may remain latent in the dog for many months, a further possible danger is incurred by injections of this animal's blood-serum into the human economy.

Your readers have already been made acquainted with the principle and technique of the new zinc chloride treatment of Lannelongue, but a few more details regarding it may not be superfluous. The best results are said to have been obtained in cases of non-suppurating joint tuberculosis. Taking a "white swelling" of the knee-joint in a child of from five to ten years as a typical example, the procedure is as follows: The joint having been previously placed in extension (and fixed in this position by means of a gypsum apparatus), and the patient having been anæsthetized, from four to six injections, of two drops each, of a ten per cent. solution of zinc chloride are made, *not* into the joint-cavity, but, first, at a short distance from the circumference of the fungous mass distending the superior synovial *cul de sac;* then one or two more injections on each side of the ligamentum patellæ, and one or two over each lateral tuberosity of the tibia, just beneath the articular border of the epiphysis, the needle in the latter case being directed parallel to the articular edge, but below its level. The solution should be deposited on the surface of, or even, if possible, beneath the periosteum, so that the needle must be pushed boldly on to the femur or tibia, and then, previous to pushing home the piston, be withdrawn a little. For two or three days after the operation (slight sloughing has in rare cases been observed after it), the joint is enveloped in a thick layer of cotton-wool maintained in position by a bandage firmly applied. In order to render this elastic pressure more effectual, layers of agaric are disposed beneath the wool over the principal points to be compressed. The beneficial effects of compression in these cases are, of course, familiar to the profession, the old Scott dressing having been long in use for the purpose. This compression is kept up for at least six weeks, when the patient is allowed to walk. In practising the injections, Lannelongue is convinced that he has more than once traversed the radial and posterior tibial arteries without any untoward consequences resulting. Whichever joint is operated on, the object is to deposit the solution, not under the skin in the areolar tissue, but on the surface of the bone, the ligaments, or the tendons. In treating tuberculous caries of the spine, the needle, which must be ten centimetres long, and not too flexible, is plunged into a spot directly beneath the apex of the transverse process of the vertebra affected, in a direction perpendicular to the corresponding spinous process, which is situated four and one-half or five centimetres to its inner side. The injections are repeated on both sides of each diseased vertebra, so that the sclerogenic solution is deposited on the surface of the body of the vertebra. The object aimed at is to provoke a sclerotic process, so as to limit, or isolate, as it were, the morbid process, and so prevent auto-infection. That this object is attained, so far as the sclerosis is concerned, has been demonstrated experimentally by Lannelongue. On the surface of the right femur of a guinea-pig, at the junction of the diaphysis and the epiphysis, three drops of the ten per cent. solution of zinc chloride were deposited. Fifty-three days later the autopsy revealed considerable thickening of the lower third of the shaft of the femur, with new formation of dense bone. Bony spiculæ were found projecting into the medullary canal; the periosteum was greatly thickened at certain points, being of a fibrous, almost cartilaginous, consistence. Lannelongue has often noticed this thickening of the femur in his patients as a consequence of the treatment. The tenderness of the bones is said to disappear rapidly.

The question arises, Is this latest therapeutical novelty doomed to be relegated to the limbo of things forgotten, like so many of its congeners, or is it destined to become classic? Time and further experience only will answer this question. The failure of Koch's tuberculin should render us cautious in rushing to conclusions regarding the value of any newly promulgated mode of treatment. The judgment passed on a remedy should be chronic, like the disease it is meant to cure. It is difficult to conceive how these sclerogenic injections can be beneficially utilized in cases of pulmonary tuberculosis. But, even should its applicability be limited to osseous tuberculous troubles, its scope is a large one, and should further experience confirm the hopes of its inventor, that enterprising, dapper little Southron will deserve the thanks of suffering humanity.

An Epidemic of Tinea Trichophytina Cruris.— Not long since an epidemic of ringworm of the thigh occurred among the members of the house staff and the nurses in a Philadelphia hospital. The starting-point of the epidemic was in the person of one of the members of the staff, but the spread of the disease to the nurses, other members of the staff, and some of the officials of the hospital, was difficult to explain. It was suggested that it may have occurred through the medium of the laundry, the linen of the house staff being washed in the same machines and on the same day, that of the nurses and officials in the same machines but on different days.

STERILITY IN WOMAN—CAUSES, TREATMENT, AND ILLUSTRATIVE CASES.

BY MARY A. DIXON JONES., M.D.,

GYNECOLOGIST TO THE WOMAN'S HOSPITAL OF BROOKLYN.

NOTHING is more beautiful than a large family of children. No greater happiness can come to a woman; and that woman is magnificently constituted, who can be the mother of such a family and still retain her health and vigor.

Children, if rightly trained, are a never-ending source of joy and comfort. Even the sound of their breathing at night is a solace sweeter than an angel's whisper; their sleeping faces are volumes of loveliness; their first call in the morning, their exhaustless questions, their thoughts—paraphrases of the mysteries of life; their keen perceptions, their constant playfulness, their never-ceasing activity, their love, their implicit confidences, all make a mother's heart rejoice, and her unspeakable love melt into tenderness; but oh, the weary solemn silence of a home without children, the stillness, the dead depression— nothing is so indescribably sad.

Planted deep in every true woman's heart is this love for children. The sacred penman again and again tells the story: Rebecca was full of sorrow because "she was barren;" the beautiful Rachel said: "Give me children, or I die;" Sarai tells her unutterable sadness in more than human words. Abraham re-echoes her grief, and in deep woe says: "I go childless; behold to me thou hast given no seed." Alone stands that cold and dreary sentence: "Sarai was barren; she had no child." Hannah prayed day and night, was in bitterness of soul and wept sore, wept and did not eat, saying, "If thou wilt give unto thine handmaid a male child!"—and when a son was given no poetry can exceed in exquisite beauty her song of thankfulness. Elisabeth was more than rejoiced when the angel said unto Zacharias: "Fear not; thy prayer is heard, thy wife shall have a son." The withering curse pronounced upon the Kings Jereboam and Ahab was, that their households should be childless; but when the prophet wanted to bless "the good woman of Shunem" with the best of all riches, it was promised that she should "embrace a son." "She had no child, and her husband was old."

A poor dispensary patient said: "Life was nothing without children." A lady of wealth, now past sixty years of age, still grieves that she has no child on which to lavish the wealth of her love. Women want these blessings. They long for these sweet little birds of Paradise, even though they have no nest, no resting-place, nor any way to make them comfortable; women of countless wealth would exchange all for the sake of one little child of their own. I have heard the moan from the depths of the human heart. Do we wonder? Alas, alas! they lose life's greatest joy.

Causes of Sterility.— Among the recognized causes of infertility in woman are:

I. *Stenosis of the Os Uteri.*—This in many instances has been the barrier that has prevented happiness, and caused heart-aching disappointment. From a very early period stenosis has been recognized as a cause of sterility. Eminent physicians have directed their best efforts to relieve the defect, or to correct the malformation. The early Egyptians studied it. More than four thousand years ago, he who "was learned in all their wisdom," repeatedly speaks of the mouth of the womb being closed, tells how "all the wombs of the house of Abimelech were closed;" and from them was withheld the fruit of the womb. Medical writers of almost every age have referred to it, Egyptians, Greeks, and Romans. Henry von Roonhyse, in his "Medico-chirurgical Observations," quaintly describes the difficulty, saying: "Who does not recollect the touching story of the little deformed woman as reported by Dr. I. E. Taylor, at the New York Obstetrical Society. She was four feet four and one-half inches. Five years previously she had been delivered by craniotomy of a child that weighed eleven pounds. Again becoming pregnant, she determined to take whatever risks might be necessary for the sake of having a living child, facing the dangers of a Cæsarean section, even when told her chances were only fifty per cent. We equally admire her desire for children, her dauntless courage, and her more than ordinary heroism." "The neck of the womb is very narrow, hardened, and tapering out, and comes to be shut very close, and even so close that a thin stiletto will not pass into the bottom of the womb; by which infirmity the womb remains shut, the neck comes to be swollen together."

The same writer speaks of a cure by the "violence of the knife;" and in 1650, Joannis Schultetus, in his "Instrumentorium Chirurgicorium," pictures a uterotome, copied probably from some prior work, or more ancient record, for, at a very early period surgery was resorted to for relief. In modern times probably the first to popularize surgical procedures for stenosis and flexion was Sir James Y. Simpson, of Edinburgh, and by his bold, bilateral discission of the cervix, he made many cures. When stenosis is combined with anteflexion, the operation suggested by the keen intuition of Marion Sims, viz., "posterior section," will more completely meet all the indications, and is more effectual and safer.

Among the first patients who consulted me in my earliest practice were many who came to know why they did not have children. In some I found stenosis of the os, and when, as far as I could then judge, there were no complications, I used bougies, or sponge-tents to dilate. No doubt success in many instances was insured by reducing the inflammation of the cervical mucous membrane, whose somewhat swollen condition possibly obstructed the os and the already diminished calibre of the cervix. One of the most marked cases was Mrs. C——, a beautiful woman, who sought, in 1870, medical aid on account of a persistent sterility. I found stenosis of the external and internal os, the cervix was "narrow, hardened, and tapering out," and there was more or less congestion and inflammation of the endometrium. After reducing the inflammation, I used graduated sponge tents, keeping each one in about twelve hours, and on removal, swabbed out the whole internal surface of the cervix and of the uterus with a strong carbolic acid solution. The sponge-tents did not cause the least disturbance, and in eleven months thereafter the patient gave birth to a healthy male child.

About the same period I treated another young woman by the sponge-tents, her sterility was cured, and subsequently she gave birth to several children. Soon after, a patient with similar conditions consulted me, but after my best-directed efforts by treatment and by sponge-tents, she remained sterile; the cause, I am now convinced, was a catarrhal salpingitis, sufficient at least to

prevent the efficient action of the tubal cilia. Still the use of the sponge-tents, with careful antisepsis, promoted drainage, and thereby the patient's local condition and general health were greatly improved.

In 1876 Mrs. D—— consulted me. For many reasons she wanted to bear children. Local medication, while it improved the patient, did not seem to remove the cause of sterility. I requested Professor T. G. Thomas to see the patient. He considered her condition unpromising, yet advised a continuance of the treatment for the uterine catarrh, which I did and, at intervals, used three or four sponge-tents. The patient improved and subsequently became a mother.

Thus, in many instances, I have found sponge tents have been of valuable service; the temporary pressure has stimulated the endometrium to healthy action, and has had an alterative effect upon the whole uterus;[1] but without care sponge-tents may be a source of grave danger, the fibres of the relaxing and infectious sponge may so penetrate into the yielding mucosa, so bury themselves into the tissues, as to imbed pyogenic germs, and cause serious disturbance, and even dangerous conditions.[2]

Dilatation of the cervix, whether rapid or gradual, is a much cleaner operation, more surgical, more effective, and safer, and does especial good in that it more successfully promotes drainage, and thereby has a favorable effect upon the uterus and the uterine adnexæ;[3] yet if this operation, however simple it may seem, is not done aseptically or antiseptically, it may result most disastrously;[4] while, if carefully and properly performed, it does good in many ways and helps to secure favorable results in several other operations, as in curetting, trachelorrhaphy, etc. I have dilated the cervix near three hundred times, and in no instance have I had an untoward result, or even a rise of temperature.

But I have been led to query if, after all, whether "stenosis of the os" was in itself a cause of sterility. I have seen women with a markedly small os, who have borne children, and in a few instances, the os has remained small and virgin-like after several parturitions. Still a contracted os is more easily obstructed; so dilating, or removing any impediments or obstacles, will make conditions more favorable for conception. Even an accidental plug of mucus may block the passage, as we know that simply passing the sound has in some instances removed a temporary sterility. In like manner, polypoid growths in the cervix may effectually close the canal and be a cause of infertility. One patient had been married eight years and was sterile; I removed from the cervix two small pedunculated mucoid tumors, in ten months thereafter she gave birth to a child. That stenosis is at least unfavorable for conception is proved by the fact that many women who have been sterile for years have, after dilating the cervix, borne several children in quick succession.

II. *Flexions of the Uterus.*—Anteflexion of the body or of the cervix is frequently found associated with stenosis and with an elongated cervix. For the anteflexion, posterior section with anterior incision has effected most remarkable results. It corrects in a degree the deformity, straightens the curve, renders the canal patulous, and thus in many instances the difficulty has been removed.

One of the first patients for whom I performed this operation was Mrs. W——, who consulted me in 1876 for sterility. The cervix was acutely anteflexed, and there was stenosis of both the external and internal os. I made posterior section and anterior incision, under full antiseptic precautions, put in the intra-uterine glass stem, tamponed for three days, then introduced the cup-shaped pessary. The patient recovered without a bad symptom, became pregnant a short while after, and in due time I delivered her of a well-formed, vigorous child, and there was no laceration of the cervix.

Some have thought that patients who have had stenosis were more liable to cervix lacerations. But stenosis of the os, when not the outcome of disease, or caustic treatment, is not a cause of, nor does it predispose to, lacerations of the cervix. I have demonstrated by microscopical examination that lacerations occur in those cases where a previous inflammation has transformed portions of the muscle-fibre into fibrous connective tissue, which cannot expand, and consequently, during a strong uterine contraction, breaks or tears; hence the laceration.[1]

It has also been said that a person who has had the operation of cervix incision is liable to abort. This is equally incorrect. I have never known an instance, nor do the circumstances justify the conclusion.

The next patient for whom I operated by posterior section for anteflexion was Miss R——, in 1876. Her dysmenorrhœa was so severe, and the reflex irritation to the nervous system was so great, that her friends and many of her schoolmates thought that her mind was becoming affected. In the treatment of this case I had tried sponge-tents without good results, so decided to make posterior section of the cervix. This was done under full antiseptic precautions. The patient did well, there was no hemorrhage nor rise of temperature, the dysmenorrhœa was relieved, she was less nervous, and there was a great improvement in her mental condition, so much so, her father said "she was another girl." Not a great while after, this young lady was married, and within a year she gave birth to a child.

Miss S—— had an undeveloped, retroverted uterus; the cervix was acutely anteflexed at the internal os, dysmenorrhœa was very severe, and her nervous system and mental condition were morbid. I lifted the uterus in position, and so extreme was the flexion that to straighten the canal it seemed necessary to make posterior section; after which I introduced the intra-uterine glass stem, and subsequently a pessary to hold the organ in position. The patient's sufferings were in a measure relieved and her general health, nervous, and mental conditions were greatly improved. The operation corrected not only the deformity, but stimulated the infantile uterus to healthy action. Afterward this young lady married and had a family.

In 1868 Mrs. A—— consulted me in regard to her sterility. She had stenosis of the os, anteflexion of the cervix,

[1] The first sponge-tents I used were presented to me by Dr. T. A. Emmet, as he had them prepared for his own use, and in this I was most fortunate. At that time I was studying most assiduously the surgical works and writings of Marion Sims and T. A. Emmet, also was privileged to see Dr. Emmet and other surgeons perform many operations.

[2] Dr. H. P. C. Wilson says: "I have lost one patient from the use of tents after the greatest antiseptic precautions, and have had a number ill from peritonitis and cellulitis following tents." Dr. T. G. Thomas said: "I have seen several deaths due to the use of sponge-tents. I never use them now, but employed them up to two or three years ago" (Lectures, 1889-90, p. 106).

Marion Sims said in 1887: "Pelvic cellulitis is more frequently produced by a sponge- or laminaria-tent than by anything else."

Dr Robert Barnes, of London, says: "Numerous cases have occurred of pelvic cellulitis or peritonitis, and some of septicæmia, from the use of sponge-tents."

Dr. L. G. Harrison said in the New York Obstetrical Society, February 3, 1891: "Before the time of antisepsis the use of sponge-tents was frequently followed by a parametritis, as I have had frequent opportunity of observing. In cases in which septic peritonitis follows the employment of tents, the patient usually died" (American Journal of Obstetrics, April, 1891).

Gill Wylie said, in the MEDICAL RECORD, July 25, 1891, "he was satisfied that the use of sponge-tents was a more dangerous practice than the performance of laparotomy."

[3] Professor Gill Wylie performs it frequently and successfully. Dr. Goodell reported on one occasion that he had done it three hundred and nineteen times. Dr. Moore Madden's paper at the last International Congress favors it for obstructive dysmenorrhœa.

Dr. Charles Meigs Wilson wrote me, September 6, 1890: "My father believed in gradual dilatation of the uterus instead of rapid dilatation, or, as he sometimes used to call it, 'divulsion of the uterus.' For the cure of dysmenorrhœa, the relief of sterility, and for intra-uterine applications, I almost universally employ this method. The results have always been satisfactory, and I have never met with an accident. I have done considerably over five hundred."

Dr. Elwood Wilson has performed this operation over five thousand times without unfavorable results.

[4] Dr. T. G. Thomas said, in 1886: "Dilatation should be practised with antiseptic precautions, as minute and strict as to details as when used for laparotomy," adding "I have treated many hundreds of cases of anteflexion in this way, and many times have been alarmed by high temperature, making the threat of septicæmia, and twice have had pelvic abscesses develop."

and suffered with dysmenorrhœa. Posterior incision was made; the second day after, Professor T. G. Thomas saw the patient, he thought the operation very satisfactory, and that it would be followed by the best result. The patient made an excellent recovery without a bad symptom; yet in all the years since, even with the cumulative treatment of other physicians, she has had no children. I am now convinced that her case was complicated with salpingitis, and it was the ulterior cause of her sterility.

The next patient for whom I performed this operation was a woman of eminent social position. Incidentally I mentioned the intended operation to Professor B. F. Dawson, of New York; he said he considered the operation exceedingly dangerous; at that time he knew a woman who was dying in consequence of it, and had known of several deaths from the same cause. I could not see then, nor do I yet, any danger in the operation if it is done aseptically, and if there are no complications, as pyosalpinx, or pelvic abscess. The deaths that have occurred, I believe, have resulted from sepsis, hemorrhage, or co-existing disease of the uterine adnexæ.[1] The operation was performed for this patient, she had no untoward symptoms, her general health was very much improved, but she remained sterile.

Why in these two cases was the sterility not removed? Each operation was carefully performed, attention given to every detail, and we had reason to expect the best results. If the flexion and the stenosis were the cause of the sterility, after these were corrected why should the sterility have continued? No doubt in each case there were other and co-existing causes.

Early in 1886, I was consulted by a young woman, Miss T——, who had stenosis and anteflexion, with dysmenorrhœa, so that her general health and nervous system were greatly affected. The uterus, thus doubled upon itself, was retroverted. I performed posterior section for correcting the deformity and straightening the canal, and then restored the uterus to position. After the operation Professor Gill Wylie saw the patient, and he thought the best results would be secured; and so it proved, not only by improving the position and condition of the uterus, but principally by favoring the health of the uterine appendages; for, as I have elsewhere stated, anteflexion of the uterus tends to develop disease of the uterine adnexæ.

The last time I performed posterior section of the cervix, was in 1887. This patient had a similar deformity; and the anteflexion had probably caused the oöphoritis, from which followed the enlargement of the ovaries, and their consequent dislocation. Posterior section gave free drainage, and thus prevented the already diseased and dislocated ovaries from becoming more and more affected, and gave them a chance to regain a degree of health.

In every instance that I have performed posterior section of the cervix, the patient has been benefited.[1] Still I believe, in most cases, dilatation of the cervix will answer the purpose and meet the indications more fully. The drainage promotes the health of the uterus, the adnexæ, and indirectly of the whole system, at the same time tends to relieve an existing sterility.

However, I began now to doubt whether anteflexion of the cervix should be classed among the causes of sterility, especially as I had observed patients who had anteflexion of the cervix, in some instances very acute, together with stenosis of the os, and yet these patients became pregnant without delay or apparent difficulty. A young married woman who, on account of an exaggeration of both of these conditions, I thought doomed to sterility, in ten months after marriage gave birth to a child, and has had one every eighteen months since, and even now, after five parturitions, there is still an anteflexion of the uterus.

Four summers ago an unmarried girl, scarce eighteen years of age, called at my office to know her condition. She had extreme stenosis and acute anteflexion of the cervix, and was two months pregnant. The scientifically branded uterus had promptly and successfully done its full duty, even against the owner's wishes, and to her great dismay. The spermatozoids can climb through devious crevices, successfully make their way, and do their work under most unpropitious circumstances.

A short time after seeing the above patient, a young married woman, Mrs. B——, consulted me for sterility. I found flexion of the uterus, stenosis of the os, and there also existed some oöphoritis, catarrhal salpingitis, and a slight displacement of the uterus and of the uterine appendages. I made no section of the cervix, used no sponge-tents, no dilatation, nor divulsion; but, in addition to constitutional treatment, I applied tampons of boro-glyceride and alum. There was great improvement in her general health, the anteflexion was corrected, the congestion and inflammation of the uterus were relieved, the neighboring engorged blood-vessels were depleted and stimulated to renewed vigor, and the patient's general health was improved. Soon after she became pregnant, and she has since had three children. Recently a patient came to me from the north of the State. She had been married some years and had no children. The pain at menstrual and intermenstrual periods was so great that she said she often wished herself dead, and considered how she might destroy herself. I gave constitutional and local treatment, dilated the cervix, used tampons, etc. She was very much improved, and a few days before her visit home, I dilated the cervix a second time, swabbed the whole internal surface of the uterus with pure carbolic acid, remarking to the patient that there might be a possibility of conception. During her stay at home she said that she had not felt so well for years, nor had she had so good an appetite. Some weeks after she returned for a continuation of treatment, and was found to be pregnant. In this case dilatation was as effective as either sponge-tents or posterior section would have been.

Dr. T. G. Thomas says: "An anteflexion is always a matter of grave significance," and in his interesting paper before the American Gynecological Society he further stated: "The wearing of heavy skirts forces the abdominal viscera down upon the growing uterus, and corporal

[1] Marion Sims performed this operation several hundred times, and lost but two cases, one on account of pre-existing abscess, the other from hemorrhage. He says further: "I consider the sponge- and laminaria-tents more dangerous than the operation." T. A. Emmet says: "It is unquestionably a dangerous operation. I have had to my sorrow pelvic cellulitis with abscesses frequently occur, and death in one instance after the most careful preparatory treatment." Dr. Emmet said on another occasion: "The operative procedure of dividing the cervix with flexure of the body of the uterus is not free from danger, for I have known at least twenty deaths that have occurred in my own practice."

Fordyce Barker says: "Sir James Y. Simpson, who had performed the operation of bilateral section many hundred times, had in one year two deaths from hemorrhage." Dr. Barker adds: "I have several times been called to see patients who, after the operation (cervix incision), were in a very dangerous condition, either from pelvic peritonitis or cellulitis. One who died had not only an accumulation of pus behind the cervix in the recto-vaginal septum, but general pyæmia."

Thomas says, in his large work, page 431: "Should this apparently trifling operation be performed during the existence of periuterine cellulitis or peritonitis the gravest results may follow, and the sufferings of the patient be greatly aggravated. Indeed, had all the fatal cases which have occurred in consequence of this operation been published to the profession, as they should have been, the list would, I think, be a startling one. I, myself, know of five, and have heard of numerous others. My conviction is that the operation, *per se*, is not attended by great danger. It is the performance of it when pelvic peritonitis exists in chronic form that has caused it to produce such bad results."

Dr. White says: "I have used Sir James Y. Simpson's instruments frequently; I did not always cure my patients, I did sometimes kill them."

Dr. Wilson says: "I have operated seventy-five or eighty times. Pelvic cellulitis in one case, and one case of peritonitis which proved fatal."

Dr. Goodell says: "I have had a melancholy result in one instance, the patient died nine days after with pyæmia."

Dr. Howard, of Baltimore, says: "Pelvic cellulitis and peritonitis will follow a certain number of cases, do what you will."

Peaslee says: "Both Sims's and Simpson's methods are dangerous from profuse hemorrhage, pelvic cellulitis, or septic peritonitis, and having a decided tendency to abortion."

[1] Dr. H. P. C. Wilson said before the American Gynecological Society: "I am convinced, after an experience in four hundred cases of posterior section that nothing which I can do can bring so much relief to the patient as this operation" (Gynecological Transactions, 1887).

flexion results. If the rectum is constantly distended by masses of fecal matter, the neck is sharply pushed forward, and cervical flexion results."

These are golden words. No organ will act as well when laced and misplaced by corsets. We cannot begin to realize the vast injury which corsets do women. As I said in an article published in *Health and Home*, April, 1871: "Tight lacing is doing more to undermine the health of American women than any other one thing." The only wonder is that it does not more seriously interfere with the functions of the genital organs and put them more out of position. We marvel that women can as well stand it. During the late war many of the Zouaves had hernia, simply from wearing tight belts around their waists.

Anteflexion of the cervix, however, in many instances, dates from the beginning of existence, or commences in feebleness of early life. Many who have anteflexed, undeveloped uteri, show the same lack of development in other respects, and frequently have not the vital power to carry on vigorously the ordinary function of sustaining life, much less the added function of maternity. Still we find instances of anteflexion of the uterus accompanying a magnificent physique, as if the latter was developed at the expense of a stunted uterus and a feeble genital organization.

Some gynecologists, in order to avoid the difficulties of a small os, or flexion, or to get clear of both, amputate the cervix. As one writer remarks: "In many cases posterior section is not sufficient; for these, there is but one resource, viz., amputation of the neck." Dr. Isaac E. Taylor said: "It is certainly to be preferred to the ordinary incision; a greater percentage of pregnancies occur after amputation of the cervix than after the operation of posterior incision." Another physician, equally eminent, says: "I have amputated the cervix a number of times, but conception has not followed in one case."[1]

Lateral flexion has by many been considered a cause of sterility. This form of flexion is undoubtedly produced by some pelvic inflammation, and the indications are to treat the pelvic trouble. If there is no peritoneal inflammation, then probably dilatation may be of some service.

Retroflexion is a more serious cause of sterility; yet even with retroflexion conception is not impossible, especially in uncomplicated cases. The uterus may be lifted and held in position by a pessary, or, more completely to overcome the difficulty, the round ligament can be shortened, or ventral fixation performed.[2]

But when there are adhesions and the retroflexed uterus is bound together, and bound to the floor of the pelvis by these adhesions, retroflexion becomes one of the most formidable and incurable causes of infertility; for the adhesions, or pseudo-membranes, are produced by repeated attacks of peritoneal inflammation, which inflammation has doubtless originated from purulent salpingitis of the tubes, a disease which, probably in every case, has destroyed their physiological functions, and thereby rendered conception impossible.

Some recommend massage for stretching the adhesions and replacing the uterus, but if the adhesions are entirely removed, and the uterus in normal position, the salpingitis will of itself be a cause of sterility, and will continue to produce repeated attacks of peritonitis, and consequent reproduction of adhesions and pseudo-membranes. Massage cannot remedy the evil, and might under some circumstances be attended with grave danger, or possibly with fatal results. In 1888, Mrs. O—— called to consult me. She had acute retroflexion of the uterus, and the uterus thus flexed was retroverted and bound together by adhesions, and by similar adhesions, or strong pseudo-membranes, it was adherent to the floor of the pelvis, while on the right was a fluctuating mass extremely sore and sensitive. I considered her condition dangerous, and advised laparotomy without delay. It was performed soon after. As previously diagnosed, the flexed uterus and uterine appendages were found in a mass of dense, well organized pseudo-membranes. These were separated, the diseased mass from each side was removed, and the uterus was lifted and stitched to the abdominal wall. The patient made an excellent recovery and is now in good health.[1]

The abscess on the right extended into the adjoining aponeurosis and was closely connected with the psoas and iliac muscles, many fibres of which were found in the specimen removed. The anterior wall of the abscess was formed partly by the remains of the tube and the ovary. So great was the destruction from the abscess that the right Fallopian tube was almost gone, only a trace of the calibre could be seen, lined by shallow folds of mucosa on the surface of which were a few vestiges of columnar ciliated epithelia,

This well illustrates the complications which may accompany a retroflexed uterus, bound with pseudo membranes, and how the anatomical structure and the physiological functions of the uterine adnexæ are in such cases more or less destroyed.

III. *Undeveloped Uteri.*—This is frequently found associated with anteflexion. Either the flexion or the lack of development may interfere with the normal functions of the uterus, and both conditions may exist in women of an otherwise splendid physical organization.

As some women do not mature until they are eighteen, instead of twelve or thirteen, years of age, naturally the same difference may be observed in the development of the genital organs; and for the time being this undeveloped or inactive condition may be a cause of sterility. In most instances it is only necessary for these organs to be invigorated,[2] the complicating disease removed, and the general system strengthened. Treated in this way, I have seen women with undeveloped uteri in time become mothers of large families of children. In 1865 a young married woman consulted me for sterility; the uterus was much below the normal size, anteflexed, and accompanied by scant menstruation. I treated her locally and constitutionally; subsequently she had a number of children.

Along with an undeveloped uterus there may be a lack of development of the ovaries or tubes, such as would be a malformation; yet these organs, even with this disadvantage, may, if healthy, perform their functions. Mrs. S—— had given birth to several children; subsequently, on account of disease, the Fallopian tubes had to be removed, and there was discovered a very anomalous condition: both were undeveloped, and bifurcated up to their union with the uterus.

IV. *Physical Overwork.*—Exhausting labor in men or women may interfere with the efficient action of any organ, as the stomach, lungs, brain, etc.; so when the system of a woman is exhausted with undue manual labor, the nervous power and vital resources used up, there may not be sufficient strength for perfecting the genital organization or for the performance of its duties. Our bodies may be made such machines of toil that not only the higher, but the procreative, powers may show a lack of activity and vigor. I have known strong sturdy women to go through such prolonged labors, such continued herculean tasks, that they had not the capability or finesse to perform the function of maternity; or sufficient *human* in them to want children. Such women are "martyrs to labor."

A German woman who visited the dispensary said

[1] Gynecological Transactions, 1876.

[2] Professor Mundé says "that in some cases when he has shortened the round ligament, pregnancy has followed." He states that he "did ventral fixation for a case of prolapsus, and the patient died, apparently from intestinal obstruction." He adds: "The result in this case took away some of my ardor for the operation; for a woman with prolapsus of the uterus should not be killed by an operation intended for its relief" (American Journal of Obstetrics, July, 1890).

[1] The abdominal fixation soon gave way.

[2] Electricity may be of service.

"that from her sixth year, she plowed, hoed, cut hay, gathered into the barns," etc. In moderation these labors might have made her strong and vigorous; they were no more severe or exhausting than much of household work, but continued eighteen hours each day, without sufficient rest or sleep, the life was taken out of the woman, and at forty years of age, after a marriage of over twenty-five years, she had no children, and still had an undeveloped uterus, already in a state of cancerous degeneration. Another dispensary patient, a strong Irish woman, with a powerful physique, almost a giant body; yet she had been such a machine of toil, that she had almost lost the fineness of womanly nature, had never been able to bear children, and her insignificant uterus was still small, infantile.

If persons who are extremely overworked and exhausted do have children, the latter frequently show a lack of power, mental and physical. Farmers, both husband and wife, naturally vigorous and strong, have been so taxed, their vital resources so drained, that there was no vitality left to give vigor to their progeny; and, in more than one instance, I have seen whole families of such children die off before their parents. Also, during pregnancy the vitality and nerve-powers may be so exhausted that there is not sufficient left for the development of the child; on the contrary, feeble women, if there is no constitutional taint, may, while pregnant, so rest and conserve their life forces and strength, that they give birth to comparatively healthy and vigorous children.

V. *Mental Exertion.*—This is given by some as a cause for sterility. How can the evil be remedied?

Dr. H. F. Campbell, in his paper before the American Gynecological Society, 1888, said: "Our female colleges and seminaries are undoubtedly successful in producing women of the highest intellectual type, but may not this modern system of education have perverted their destiny, and lessened their chances of maternity?"

Are we then to conclude that developing and improving one part of the body necessarily dwarfs another, or weakens its power and functions? Does the welfare of one organ detract from the capability of another? Does vigorous exercise to expand the lungs, weaken and injure other portions of the body? On the contrary, does not making any one part stronger, healthier, and better, improve the rest and add to the efficiency of the whole? If the roots of a tree are vigorous, will not the branches spread and the leaves bloom more beautifully? In like manner, does not making the lungs stronger, the stomach healthier, or the liver better, improve the whole human body? And will not developing the brain and nervous system give a healthier stimulus, and a better nerve-supply, to all other parts and organs?

Dr. Campbell continues: "The most unfortunate requirement of female education is the time at which it is most actively conducted, namely, from eleven to sixteen years of age, which is the period of sexual development, and of perfecting the organs of reproduction. When the years of sexual development are passed in bodily activity and without mental strain, the reproductive organs are naturally and promptly developed, their functions normally performed, gestation prosperous, parturition easy, and offspring numerous. May we not legitimately conclude that conditions so entirely opposite and adverse as these, in which the adolescent female of the better class must pass the period naturally allotted to sexual development, be considered a potent factor in the arrest of ovarian and uterine development, by diverting the vital forces from the sexual organs at the very time their exercise is most needed. The infantile uterus and atrophic sterility will be found, I think, most frequently among women who have been subjected to severe laborious and intellectual labor during the period of pubescence, than in those of any other class. The prize girl will often fulfil the destiny of a childless woman."[1]

If it can be shown that sterility and undeveloped uteri are found proportionately more frequently among educated women, among those who have gone through a collegiate course of study, "those who have been subjected to severe intellectual labor during the period of pubescence," than among women who have had no intellectual training, and who have passed the period of the development of the sexual organs in bodily activity and without mental strain, then, with some show of reason, we might seriously inquire if "severe and laborious intellectual labor," during the early periods of life, is not a "potent factor in the arrest of ovarian and uterine development;" whether it does cause "undeveloped uteri" and "atrophic sterility;" and if intellectual labor does "lessen the chances of maternity," and to that extent "pervert the destinies of women."

But is this the case? Are "undeveloped uteri" and "atrophic sterility" more frequently found among educated women than among those who have no mental training? And does mental training in girls between the ages of eleven and sixteen tend to prevent the development of the genital organs, and interfere with their functional activity?

In answer to a portion of the question, may we not refer a moment to the long array of names of brilliantly educated women who have had large families of children?

I was for years a student in the largest and most advanced college for women in this country. The students pursued a collegiate course of study embracing the higher branches of mathematics, the natural sciences, intellectual and moral philosophy, English literature, belles-lettres, etc. Many of the young ladies, besides, have heavy tasks daily in the classical and modern languages. Afterward, as a teacher I was in the college four years, and later two years in another college equally distinguished and equally advanced; and for a number of years I was principal of a young ladies seminary of a high grade, which demanded about the same course of study. During this period of thirteen or fourteen years, over three thousand young ladies came under my observation, who during the period allotted to sexual development were subjected to continuous "severe and laborious intellectual labor;" yet in all this number, and in all these years, I do not recollect a single one giving any indication that "the reproductive organs were not naturally and promptly developed, and that their functions were not normally performed." The young ladies were under my observation at all hours of the day, yet in all these years, among so many young women, I do not remember one who apparently had any difficulty with the function of menstruation, or suffered so that her studies were in the least interrupted, or that it was necessary to lie in bed, except perhaps in one instance; and this young lady did so at the periods on a few occasions, because she wanted, as I imagined, a chance to read Browning's poems, or write imitations of the same.[1]

I would have been apt to have noted any sickness, for I was then reading medicine; and besides, during all these years physiology was one of the branches that I was studying or teaching.

The young ladies who were subjected to these severe intellectual tasks grew healthier and stronger. They had their regular hours for recreation and sleep; still severe intellectual labor was demanded, equally heavy, as long continued, and for as many years as young gentlemen have at college; yet the young women were not made sterile thereby, nor invalids, nor did they lack in any way perfect development. Most of them afterward married and had large families of children.

I have known the "first honor girl" for many successive years, girls who gave themselves up to the closest and most "laborious intellectual labor," and who, for their greater mental discipline and profounder intellectual attainments, stood first. They were emphatically "women of the highest intellectual type," yet I do not know of

[1] Gynecological Transactions, 1888, pp. 442–444.

[1] This young lady graduated at the college, afterward married, and had a number of children.

any one of them who fulfilled the destiny of a "childless woman." I recollect one, with her pretty, blushing face; she married; children came in quick succession, till her table was surrounded by young and happy faces. Another "first-honor girl," always accustomed to outstripping the members of her class, when married and settled in a large city, was equally successful in outstripping her neighbors in the number of her children.

A "first-honor girl" of another school, a student, a writer, and a public speaker, yet is blessed with more than the usual number of children, and has strength to look after these children and after her household affairs, besides doing much outside work in blessing humanity. "She girdeth her loins with strength, and openeth her mouth in wisdom."

A fourth "first-honor girl," who pursued an extensive course of study, especially severe intellectual labors, was a superior mathematician, a student of five languages; this woman, at the birth of her third child, had been all day actively engaged in some intellectual pursuit, returned at nine in the evening from a walk, and before eleven o'clock all was over. She had no trouble, then, before, or after. "Gestation was prosperous and parturition easy." So of many of these three thousand and more women who were subjected to the modern system of female education. They suffered in no way from lack of development and their functions were normally performed.

In the twenty-five years I have practised medicine I have not seen a case of undeveloped or infantile uterus in a woman with a college training, or who had passed through a regular course of study, except in one instance, and this young woman, before she commenced her college course, had an anteflexed, undeveloped uterus. It was so stamped from her birth, and was by no means a consequence of much study.

On the contrary, I have seen women who have passed their younger years in bodily activity, with no college education, and a plentiful lack of mental culture, "whose reproductive organs were not naturally developed, nor functions normally performed;" who had "undeveloped, anteflexed uteri, and atrophic sterility." I have seen proportionately more cases of sterility and imperfect development in my dispensary clinics than I have found in my private practice. Many women who come to the clinics are without education, not able even to write their names, yet they have undeveloped, anteflexed uteri, which are incapable of performing their normal functions.[1]

Recently an apparently healthy, vigorous woman came to the clinic, inquiring the cause of her infertility; married nine years, and no children. Her mind had never been disciplined by intellectual labor, yet she had an infantile uterus, lying useless on the floor of the pelvis, and toppled by its side were the tubes and ovaries, equally inefficient and equally incapable of performing their functions. Many uneducated girls call at the dispensary suffering from amenorrhœa; thus in early womanhood menstruation is almost *nil;* as one said: "It lasts scarce a day, and one napkin is sufficient for the period." Others come complaining of the most distressing pains in the performance of this function, some giving evidence of arrested ovarian and uterine development, and a large number complaining of sterility produced by almost as many causes. Others again tell of suffering during gestation, and show most serious injuries as a result of "parturitions that were not easy."

Thus in many of these women, who have not been to female seminaries and colleges, or injured by the modern system of education, we "find the reproductive organs not naturally developed, the functions not normally performed, gestation not prosperous, parturition not easy, and offspring not numerous."

[1] I have been especially interested in glancing over the books of my Dispensary Clinics in 1883–84–85, to see how many cases of anteflexion and undeveloped uteri are noted and pictured as found in those poor uneducated women, who had "bodily activity and no mental strain."

One young woman who had not been afflicted with any kind of mental training, yet did not have as much as an undeveloped uterus. There was no uterus, there were no ovaries, no Fallopian tubes, no vagina, and no menstruation.[1]

I maintain, therefore, that lack of mental discipline or training does not insure or favor more perfect development of the genital apparatus, or more capability in performing its functions; nor does collegiate training or systematic intellectual labor during the period of pubescence, or at any other period, if pursued under proper hygienic conditions, interfere with the development of the genital organs, their power or functions, or lessen the chances of maternity. On the contrary, mental culture and scholastic training tend to a fuller and more perfect development of the whole body, tend to make grander women, mentally and physically, women who are more capable of bearing healthy, vigorous children, and certainly more capable of training them properly.

Mothers who have large families of children, have them, not because of lack of culture and scholastic training during the period of pubescence, but because they have good and well constituted bodies. It is a glorious thing to be well born. Besides, such women generally have full use of all the powers of the body, the organs are not cramped or bound in, nor their normal activity prevented by the cruel trammelling of corsets.

Of course we admit that excessive brain-work, overstudy, and unhealthy habits, are harmful to every vital function, and will make either boys or girls, men or women, sick.[2]

There is another fact which it is well to consider: Children without mental cultivation, with minds barren of thought, are sometimes apt to have premature sexual excitement and perverted development of these special organs, frequently resulting in weakness and exhaustion of both body and mind.

Again, every gynecologist will bear witness that diseased uterine appendages are found less frequently among educated women in the higher walks of life. To find a large practice in this department one must get their patients principally from the dispensaries or from the uneducated classes.

Diseases such as endothelioma and gyroma, in which the normal structure of the ovaries is more or less destroyed, would seem more likely to occur when the vital forces were used up in other directions. Yet out of twenty or thirty cases of these diseases I have not found a single instance in one who, in younger years, had severe intellectual labor or scholastic training.

If study prevents development, by diverting the vital forces from the sexual organs at the very time when their exercise is most needed, will not the same principle apply to boys pursuing a college course? Where is the difference? "Male and female created He them." Woman is subject to the same laws of growth and health as man, and, like him, she is capable of high mental cultivation, and may at the same time retain the full power of her procreated organs.

Dr. H. F. Campbell instances the savage, half-civilized Indian and negro women of Southern plantations. There are many Indian women who are sterile, who have anteflexion, and who suffer from consequent infirmities, and who die young on account of complications. Women's physical Paradise is not among the savage or semi-civilized Indians.

As to the negro women on Southern plantations, I was born south of Mason and Dixon's line, and I know that many of the colored women are sterile, many do not

[1] Professor B. F. Dawson saw this case with me, and had we not been convinced of the absence of all of these organs, we would have considered the question of making an artificial vagina.

[2] In the past I have written and lectured on health subjects, and one of the most urgent demands I have made to mothers was against school taxation in early childhood. The brain at this tender age cannot stand high pressure and stimulation. Children who have no special tasks until they are seven to eight or nine years of age, very soon surpass the early prodigies.

have prosperous gestation or easy parturition, nor numerous offspring. It was among these women that Marion Sims was led to study the remedy for vesico-vaginal fistula, proving that parturitions among them were not always "easy" or "prosperous."

Properly educating and training the mind does not render any other organ less capable of performing its normal functions. To insure the highest degree of development both bodily activity and mental culture are essential.

VI. *Misplacement of the Uterus.*—This has in unnumbered instances been a cause of sterility. In many I have placed a Hodges pessary to correct retroversion, and women who had previously been sterile for years conceived.

More than a dozen years ago a young woman consulted me, suffering locally and in general health, but most grieved that she could not bear children. Her only child, born nine years previously, had died in infancy. I found a deep transverse laceration of the cervix, retroversion of the uterus, and a torn perineum. I replaced the uterus preparatory to repairing the injuries, but before I had an opportunity for so doing the woman became pregnant. In another one, who had extreme prolapsus of the uterus, and for years an acquired sterility, likewise, upon replacing the uterus preparatory for certain plastic operations, pregnancy supervened. I believe the little sagging, or a slight dislocation, of the uterus has, in thousands of women, been the cause of prolonged sterility. Still a misplacement is not always accompanied by infertility. In 1876 a young married woman, Mrs. D——, consulted me. She was then three months pregnant, and the uterus completely retroverted. From her clinical history there was no doubt the retroversion existed before marriage. I replaced the organ, put in a pessary, and she went to full term.

About the same time I had two other patients with similar conditions, both of whom were in the fourth month of pregnancy, and both had extreme retroversion of the uterus. Fearing that, in replacing the uterus, there might be some untoward accident, I requested Dr. Z. Emery to be present, and he was in each instance. Both patients did well and went on to full term.

In 1890, Mrs. M——, then in the fourth month of her ninth pregnancy, consulted me. She had complete retroversion of the uterus, and a deep transverse laceration of the cervix. I replaced the organ, put in a "Thomas Cutter,"[1] and five months after delivered her of a healthy male child.[2] No doubt the conception occurred while the uterus was in malposition. The long-existing laceration had prevented involution, and produced increased hyperplasia of the uterus, which caused the persistent misplacement.

A yet more extreme case, Mrs. C——, came from a neighboring town; said that she supposed herself five months pregnant, but was in no way increased in size. The enlarged uterus was retroverted, and impacted in the pelvis. I informed the patient that it must be lifted into position, but in doing which the life of the child would necessarily be imperilled; that I would not attempt to replace the organ in my office, but the next day would visit her in her home. This I did.[3] The uterus at first seemed firmly fixed and impacted, but by careful manipulation it was moved and gradually restored to position, and pregnancy went on to term. No doubt conception occurred while the uterus was displaced.

VII. *Lacerated Cervix.*—This may be a cause of sterility, first, from the resulting inflammation and change of the cervical and uterine mucous membrane; second, from a weakened, relaxed, and hypertrophied state of the whole organ. By repairing the laceration the uterus is made healthier, and thereby sterility may be cured.[1]

Mrs. —— consulted me in 1885, being a sufferer locally and in general health, and had an acquired sterility of some eight or ten years' duration. There was an extreme bilateral laceration of the cervix, lips everted, and the mucous membrane covered with small erosions, some portions of which were in a state of deep ulceration, bleeding at the slightest touch. I repaired the laceration.[2] The patient made an excellent recovery, and after the operation the uterus presented an entirely normal appearance. The patient's health was very greatly improved, and soon after, in quick succession, gave birth to three children. Thus repairing a lacerated cervix, when there is no pelvic trouble, improves the general health, prevents untoward results, and in unnumbered instances has removed an acquired sterility.

A writer in the *American Journal of Obstetrics* in January, 1883, says: "I have endeavored to collect all the cases where, after this operation, conception took place; fancy my astonishment to find throughout all the literature of the Surgeon-General's office, touching this particular point, eleven cases only recorded."

I think if the doctor will examine every-day life and practice, he will find unnumbered instances of conception following trachelorrhaphy, and due to the good results of the operation. When it is properly performed the uterus becomes more healthy, and consequently more capable of performing its functions. In 1882 I restored for a patient, in the Woman's Hospital and Dispensary, a deep transverse laceration of the cervix; subsequently she had a number of children. Mrs. R—— was a patient in the same hospital, had a similar laceration, and was sick and suffering in her general condition. If the injury had not been repaired she would have continued to be sick, having constantly more or less distress, and would have remained sterile. The operation was advised, not however on account of sterility, but because of her local suffering and enfeebled health. She made an excellent recovery, and afterward had five children. Mrs. McM——, in the same hospital, had also a deep transverse laceration of the cervix, which was restored with equally good results.[3] A few weeks after, when I repaired the perineum of this same patient, Dr. J. H. H. Burge, Dr. F. W. Rockwell, and Dr. Colton were present, and had an opportunity of seeing the already restored lacerated cervix; as one of them remarked, "the result was perfect." After the operation the patient's health was very much improved, and subsequently she had several children.

In 1883 Mrs. D——, from a neighboring city, consulted me for sterility and pain. Thirteen years previously she had had a child, at which time occurred a deep transverse laceration of the cervix. I repaired this injury,[4] and the patient has subsequently given birth to five children. Many such instances I could narrate. One of the most interesting of the kind was a friend of the last-named patient. Her only child, born five years previously, had died in infancy. I found an extreme laceration of the

[1] This pessary is especially serviceable when there is no perineum.

[2] Two months after I repaired for this patient the cervix and perineum. Dr. Annie Brown and Dr. Harriet Pilsbury were present; one administered the ether and the other held the speculum. Dr. C. N. D. Jones assisted in the operation.

[3] I had clearly in my mind the case mentioned by Montgomery, where a woman had died in this condition, and after death the pregnant uterus was found so wedged in that the pelvic bones had to be sawn asunder before it could be lifted.

[1] Dr. Joseph Price, in his timely and able article published in the Buffalo Medical and Surgical Journal of November, 1890, shows how major pelvic troubles are often traceable to minor gynecological operations. Any minor operation of the cervix, if not done aseptically, may result in serious pelvic trouble. When the operation of restoring a lacerated cervix is performed a patient should recover in eight or ten days, and she will if there is no sepsis. If she does not, and if, as in some instances, she is sick for weeks in consequence of the operation, mischief is done, or in the emphatic words of Dr. Price, "the person is made distinctly worse by operative interference." I have in delicate women cut from the cervix large portions of diseased tissue, brought together the great flaps, and in a week the wound was entirely healed and the patient comfortable. Dr. Price wisely reminds us that when there is pre-existing disease of the pelvis no cervical operation should be attempted.

[2] Dr. C. N. D. Jones assisted. Dr. Samuel King administered the ether, and Dr. Josephine Dupre held the speculum.

[3] In the last three operations ether was administered by Dr. A. H. P. Leuf, Dr. C. N. D. Jones assisted in the operation, and Dr. E. J. C. Minard was present.

[4] Dr. Conway and Dr. C. N. D. Jones were present and assisted.

cervix, on one side, extending past the vaginal junction. The operation of trachelorrhaphy was performed, and in less than a year the patient gave birth to a child, and has had two children since. In 1885 Mrs. C—— was a patient in my private hospital, she was in a very depressed state of health, and had a deep transverse laceration of the cervix. I restored this laceration in the presence of several physicians, who were at that time attending the New York Polyclinic. The operation was successful in every respect.

Mrs. Y——, suffering from a similar condition, was, in 1888, operated on in the Woman's Hospital of Brooklyn, and the only reason why she wanted the operation was to remove an acquired sterility of nine years' duration. So, many instances could be given where the operation has resulted satisfactorily in this respect, and probably it would in every one, if there were not other and pre-existing causes of sterility. Consequently there will sometimes be a disappointing result.

In 1876 I performed this operation for Mrs. L——, on account of acquired sterility of some years' duration. Dr. C. N. D. Jones assisted. Dr. Z. Emery administered the ether. The patient was young, and in some respects seemed to be a favorable case, but the sterility was not removed, because, as I now know, there was tubal disease. So another patient, Mrs. Y——, had an acquired sterility of nine years. The lacerated cervix was repaired, but the sterility continued.[1]

While a lacerated cervix is often a cause of infertility, still we know it is a fact that some women are exceedingly fruitful who have laceration of the cervix to such a degree that it is a question whether there is sufficient vantage ground to hold the fœtus. A patient consulted me who had an extreme bilateral laceration, yet had nineteen children, and evidently the laceration had been existing some years. Another woman, who had an old laceration, had fourteen children; another sixteen, and one woman had a similar deep bilateral laceration of the cervix, and was then pregnant with her thirteenth child. Though a laceration in these cases did not cause sterility, yet it was a cause of suffering locally and constitutionally, and in depressed states of the system it may be a cause, and become the seat, of a malignant growth. Attention was drawn to this fact more than twenty years ago by Dr. T. A. Emmet.

VIII. *A Lacerated Perineum.*—A lacerated perineum is frequently a cause of sterility, by producing more or less displacement of the uterus and the uterine appendages, and consequent disease and functional disturbance. So, repairing the injuries has in many instances resulted in normal functions.

IX. *Fungoid Growths.*—In this condition we find the mucous membrane thickened, the utricular glands diseased, and consequently the uterus cannot as well perform its normal functions; besides which, the repeated hemorrhages may be a cause of sterility by preventing the fixation of the ovum.

Mrs. H——, after the birth of two children, had become sterile. The frequency and duration of menstruation continued to increase until she had well-pronounced menorrhagia, and finally it became dangerous hemorrhage. I curetted the uterus, removed a large amount of fungoid tissue—the hyperplastic mucosa—after which the menstrual flow was normal, and in two months the patient conceived.

Mrs. G—— was brought to the Woman's Hospital of Brooklyn in an almost dying condition, perfectly ensanguinated, lips blanched and pulse rapid. She was forty years of age, and had been sterile for a number of years. That evening, after attending to a number of patients, I was about leaving the hospital, then past ten o'clock, when seeing the woman in apparently so dangerous a condition, I did not consider it safe to leave her until the next morning, so had her placed upon the table, curetted fully the whole internal surface of the uterus, and swabbed it out with pure carbolic acid. The patient had no more hemorrhage, gained strength rapidly, and a month or so after leaving the hospital conceived.

In 1865 I had a similar case of long-existing sterility with hyperplastic mucosa; finally the patient was taken with profuse and apparently dangerous hemorrhage. I requested Dr. Louis Pilcher, of Brooklyn, to see the patient with me; said to him that I thought it was fungoid growths, and that they should be removed and thereby the hemorrhage stopped. But so aggravated was the patient's condition that Dr. Pilcher judged it was cancer, and that "the history of the case would be repeated hemorrhages until she died." The hemorrhages becoming more dangerous, I requested Dr. T. G. Thomas, of New York, to see the patient. He diagnosed fungoid growths, and at my request removed them. The patient recovered and is still in good health.

X. *Diseased Ova.*—I have not yet seen the condition of the ova mentioned as a cause of sterility, yet it is a serious and frequent cause, and no doubt is the secret why, in many instances, well-directed efforts to cure sterility have been unavailing. I have been surprised, in studying the morbid anatomy of the ovaries, to find how frequently the ova are diseased and abnormally changed. I first recognized the condition in the ovaries of a patient who consulted me in 1887. She was twenty-seven years of age, had been married six years, had no children. The patient was sad and broken-hearted, not so much because her health was wrecked, that she was emaciated, pale, and cadaverous, suffering pain, and not able to work or attend to her household duties, but because she could not have children. She had had excellent medical treatment by many physicians, was no better, but rather grew worse. There was serious disease of the ovaries—manifestly some unusual form of degeneration—that with me it was not a question of having children, but to save the woman's life, and trying to restore her to some degree of health. I informed the mother and husband that I did not believe anything would cure the patient or prolong her life but the removal of the diseased structures, which evidently were becoming more and more seriously affected. These were removed, the patient made a good recovery, and afterward, by microscopical examination, it was verified that almost the entire stroma of both ovaries was destroyed by an endotheliomatous growth, and the ova were found in varied forms of degeneration. Some were filled with medullary corpuscles, without a trace of the yolk, or the macula germinativa; in others the macula germinativa and the vesicular germinativa were broken down into granular matter, and the few epithelia that remained were enormously swollen or contained fat granules. In others, again, the work of destruction was still farther advanced by the yolk being changed to fibrous connective tissue. In many places the only remains of an ovum or of closely packed groups of ova were clusters of inflammatory corpuscles, changing to fibrous connective tissue.

The ova showing these various stages of a retrograde process were in the midst of newly formed myxomatous tissue, which was again taking on a new inflammation, or changing to inflammatory corpuscles, other portions to fibrous connective tissue. What was more striking still, many of the ova were being penetrated by the newly formed myxomatous tissue, and soon there would have been left not a vestige of the original ova.

The indications were that this woman, but for the changes in the ova, would, before the more serious advance of the disease, have been capable of bearing children.

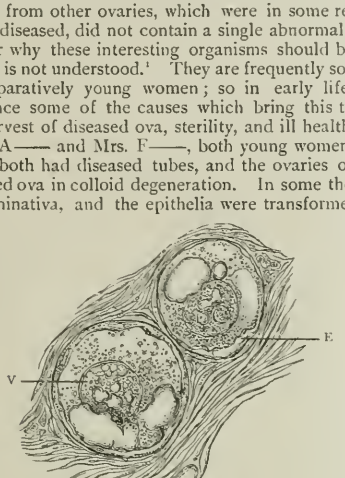
Diseased ova were next found in a patient who had pyosalpinx, and who during her whole nine years of married life was sterile. Apart from the salpingitis, the condition of the ova would have been a sufficient cause of infertility. Some of them were in a state of intense acute inflammation, some were in fatty degeneration, shrivelled, or so atrophied that there was not one anatomical element

[1] Dr. Carey administered the ether; Dr. J. H. H. Burge and Dr. C. N. D. Jones assisted.

of the original ova to be found. In one field of the miscroscope I counted as many as fifty, all shrivelled and partly waxy. No treatment or medication could have brought these ova back to health or normal activity, consequently, even apart from the salpingitis, nothing could have cured the patient's sterility.

It may here be remarked that while sections from some ovaries exhibited an almost entire destruction of the ova, sections from other ovaries, which were in some respects equally diseased, did not contain a single abnormal ovum. How or why these interesting organisms should become affected is not understood.[1] They are frequently so found in comparatively young women; so in early life must commence some of the causes which bring this terrible after-harvest of diseased ova, sterility, and ill health.

Mrs. A—— and Mrs. F——, both young women, both sterile, both had diseased tubes, and the ovaries of each contained ova in colloid degeneration. In some the yolk, the germinativa, and the epithelia were transformed into



Colloid Degeneration of Ova. × 600. V. Vesicula germinativa, with small colloid lumps; E, epithelium in colloid degeneration; L, colloid lump in the muscle-layers of the ovary.

colloid corpuscles. In others the entire centre of the ova was a colloid mass.

Such colloid lumps as L (see illustration) were found in great numbers in the muscular fibres, cyst-walls, invading the ova, and even scattered among the pigmented corpuscles of a recent menstrual follicle. They must be of some significance, or a cause of disturbance, as all the women in whose ovaries they were found had a history of suffering, and most of them were sterile.

Mrs. —— when first married was strong and in perfect health, had two children, since which time for more than ten years she has been sterile, suffering locally and constitutionally from disease of the uterine appendages, also by reflex irritation her mental conditions were at times disturbed. The ovaries and tubes on both sides were enlarged, sore, sensitive, and prolapsed in Douglas cul-de-sac. They were removed, and subsequent microscopical examination showed that there was subacute oöphoritis, and the ova were found in all stages of inflammatory action, many advanced to waxy degeneration. In one follicle there were four ova, and all waxy.

Another patient who had been sterile for years, and although the ovary was almost entirely destroyed by an endotheliomatous growth, yet at one period it was the diseased ova that caused the sterility.

XI. *Disease of the Ovaries.*—In disease of these organs we find many and varied causes of infertility. Besides abnormal ova we have acute, subacute, chronic, and intestinal oöphoritis, benign and malignant growths, and, as an outcome of previous existing disease, dislocation of the ovaries.

Acute, subacute, chronic, or interstitial oöphoritis, when intense, will change any and every structure of the ovary; the smooth muscles will be transformed into fibrous connective tissue, producing more or less cirrhosis of the organ, which necessarily interferes with the functions, and consequently will be a cause of sterility.

[1] I am still pursuing my microscopical investigations to understand the etiology and pathology of diseased ova.

In the normal ovary there is a vast amount of muscle-tissue,[1] placed there for some purpose, possibly to help in maturing the follicles of De Graaf, or to help their growth toward the surface, or to help in the extrusion of the ova.

Another cause of sterility is benign or malignant growths in the ovary; they destroy the normal structure, or produce more or less displacement of the organ, and thereby its natural relations with the tubes are lost.

Dislocation of the ovary is also a cause of sterility, as it prevents the easy co-adaptation of the ovary with the tubes. But as the dislocation most frequently results from oöphoritis, or the consequent hyperplasia, or from abnormal growths, these, then, are really the cause of the functional incapability.

A more serious cause of sterility is the formation of pseudo-membranes covering the surface of the ovary, as illustrated in Fig. 5, in "Microscopical Studies in Peritonitis." Such pseudo-membranes, or dense fibrous connective tissue, result from salpingitis, oöphoritis, or local peritonitis, and will prevent the exit of the ova from the ovary. These little organisms, of microscopic smallness, carrying their wonderful load of living matter with its vast capabilities and powers of growth, when they start on their perilous journey from the ovary to the tubes, may meet with yet greater difficulties, even insurmountable obstacles in the dense membranes that may envelop, bind down, and close the tubes; thus, many of these little beings, these marvellous masses of living matter, are lost and perish.

Schroeder speaks of "the external migration of the egg;" that is, its passage from one ovary to the tube of the opposite side. But can the ova make the supposed journey? Have they any way of locomotion or means of progress? If it takes ten or fifteen days for one to pass through the Fallopian tubes, it would be months in making such a voyage as this, a voyage so full of pitfalls and so perilous that scarcely a single ovum would ever arrive safely at the end of its Don Quixote expedition.

Is it not more likely that the countless millions of cilia in the tubes create a current sufficiently strong to draw the egg into its pavilion, or into the fimbriated extremity of one tube or the other; and then by peristaltic action of the tubes the egg is floated or blown along. Or, probably the Fallopian tubes, with their wonderful muscular structure and marvellous capability of motion, may fix themselves first upon one ovary, then upon the other, so that an egg from one side will pass through the tube on the opposite. This is not improbable, and may explain what is supposed to be the "external migration of the egg." The Fallopian tubes have wonderfully thick layers of muscles, both longitudinal and transverse—a richer supply than have the walls of the alimentary canal. It has been demonstrated[2] that they have in their walls five layers of muscles instead of three, the number usually given by anatomists. So the Fallopian tubes are capable of varied and extensive movements, and either may fix itself upon the ovary of the opposite side.

Of all causes of sterility the diseases of the Fallopian

[1] Many standard and well-known authors do not mention the presence of muscles in the ovaries. Professor J. C. Dalton, in his well-known Physiology, says: "The ovary is comparatively simple, consisting only of Graafian follicles united by connective tissue: in man the connective tissue is denser and more abundant." The American System of Obstetrics, vol. i., p. 68, says: "The adult ovaries are dense, fibroid, ovoid masses. The stroma consists fundamentally of a close felt-work of hard, fibrous, and yellow elastic connective tissue richly supplied with muscle-corpuscles." Another writer refers to "the much-vexed question as to whether smooth muscle-fibres do or do not exist in the normal ovary." Without doubt in the normal ovary there is much smooth muscle-fibres, in the cortex especially, where the muscle-bundles gracefully wind and intertwine in wonderful complexity; nor are they, according to His, "stunted muscular fibres." Can we regard the ovary as "comparatively simple" in its structure? Is it not rather a complex organization with a great variety of tissues? As Dr. H. C. Coe, in his erudite article on "Fibromata of the Ovary," published in the American Journal of Obstetrics, July, 1872, says, it is "an organ which abounds in inexplicable things—anomalous appearances so frequently encountered, at whose pathological import we can merely guess."

[2] In Dr. Heitzman's laboratory.

tubes are by far the most frequent and the most serious. The health of no organ is more essential to fertility. The uterus may be lacerated, ulcerated, anteflexed, retroflexed, enlarged, displaced, cancerous, or the seat of fibromatous growths, yet if the Fallopian tubes are healthy conception is possible. The ovaries may be dislocated, and the seat of varied forms of degeneration, the woman hysterical, have painful menstruation and pelvic pains, yet if the carriers of the egg are healthy all may be well. I have seen a healthy ovum in the midst of a sea of ovarian disease; such an ovum, if the tubes are all right, may accomplish its full destination. But when the tubes are diseased, the mucosa thickened, swollen, or converted into masses of inflammatory corpuscles, the walls changed, its muscular structure destroyed, the fimbriated extremity closed, and possibly the whole tube converted into an abscess, then the tubes are no longer capable of performing their functions. They are physiologically dead. The woman is completely and forever sterile. As well talk of one who is stone-blind seeing the fine colors of the rainbow.

In performing laparotomy one often observes that the uterine appendages on one side are more profoundly diseased than are the uterine appendages on the opposite side, also unmistakable evidence that the disease has existed a much longer period on one side than on the other. Sometimes the appendages on one side may be almost normal, while those on the opposite are so thoroughly diseased as to be incapable of cure, or of performing any physiological function.

It is also a fact that if the uterine appendages on one side are seriously diseased, it will interfere with, and probably prevent, the more healthy organs on the opposite side from performing their normal functions; and what is still more remarkable, the diseased organs on one side will sooner or later involve or cause the more healthy ones on the opposite side to become diseased. If, before this takes place, the already diseased appendages are removed, the remaining ones may become more healthy and more capable of performing their functions, and thus a woman who would otherwise remain sterile may, by the operation, become fruitful and bear children.

Mrs K—— came to the dispensary of the Woman's Hospital suffering in general health, pain in the pelvis, and evident disease of the uterine appendages, and was sterile.

The uterine appendages on one side were much more diseased than on the opposite. We judged by removing the more diseased organs the less diseased would grow more healthy, and, for a while at least, be able to perform their functions. The operation was performed April 16, 1889. The patient made an excellent recovery, and was continued under special treatment till June 26th of the same year, when she left the hospital. On June 20, 1890, she was delivered of a healthy female child. August 3, 1891, she was delivered of a second child, and without any indications of strain on the abdominal walls. The patient is now in excellent health, with probabilities of having several more children.[1]

If the uterine appendages which were diseased had not been removed, they would in time have affected those on the opposite side, and thereby hopeless sterility would have ensued. By the operation the patient was relieved of pain, restored to health, and made fruitful.

The advantage of a unilateral operation, as to fruitfulness, is often illustrated in the removal of a cystoma, after which, as repeatedly proved by clinical experience, a woman who was previously sterile is capable of becoming pregnant.

Conclusion.—Sterility results from disease or defective formation, the indications are to cure the disease and correct the defects.

[1] An instance is given of a woman who had the uterine appendages only on one side, yet she had nine children. I have counted in one microscopical section seventy-three good ova.

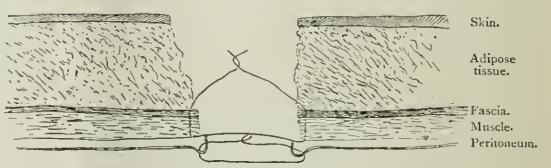
THE PREVENTION OF VENTRAL HERNIA AFTER ABDOMINAL SECTION.

By W. R. PRYOR, M.D.,
NEW YORK.

When I recently reported to the New York Obstetrical Society cases illustrating my method of treating the parietal wound after abdominal section, I scarcely thought the important but simple procedure would attract so much attention.

One result of the discussion about it has been to bring to light a great many cases of ventral hernia, and to convince me that many women have it who should have escaped that most troublesome sequela of the operation. In conversation and discussion upon the subject, my surgical friends have confessed the acquaintance of so large a number of these unfortunates that I am persuaded they exist in a most distressing percentage.

I can conceive of no excuse for this accident after abdominal section, except in one class of cases. Here it is perfectly natural to expect it, viz., in cases where the pedicle must be treated externally. No little blame for these ventral hernias attaches to the manner in which many surgeons make the abdominal wound. The incision through every layer of the parietal wall, except the peritoneal, should be made with the knife. Yet how often do we see operators clipping a little tissue with the scissors, then cutting a little more on a grooved director, or inserting two fingers and tearing the tissues apart in that way! It is as absolutely necessary to primary union, here as elsewhere, that we have clean-cut and smooth edges to approximate. Another error into which the surgeon, operating perhaps against time, is apt to fall, is that of bringing together the edges of the wound before all bleeding has been controlled. Hæmatoma and pockets of blood are frequently the cause of partial and incomplete union.



But granted that the abdomen has been opened in the most approved manner, and the operation so completed that there exists no necessity for a drainage-tube, shall the surgeon, in all cases, bring together by one set of sutures all the layers of the parietes—skin, fat, fascia, muscle, and peritoneum? I have formulated for my own guidance the general rule that when the belly fat is over an inch thick I will treat the wound by my method. I do this not so much because of my belief in the uselessness of union between fat surfaces, as because I am convinced that to do otherwise I run two risks: either I fail to accurately coapt the fascial and muscular edges, or else, in tying the sutures with force sufficient to bring together the deeper layers of the parietes, I strangulate the fat surfaces. The abdominal fat is but poorly supplied with blood-vessels, and where it is at all excessive, sutures tied sufficiently close to approximate the fascial and muscular edges must of an almost necessity produce mural abscesses. Years ago I recognized this fact, and attempted to prevent the occurrence, in fat women, by introducing between the sutures pieces of small drainage-tubing. But I succeeded partially only. These mural abscesses hardly deserve the name. At first they contain little other than liquid and broken-down fat. The strangulation of the fat by the sutures may not be sufficient to produce abscess, but merely a degree of inflammation which prevents firm union between the fascial and muscular edges Both the formation of mural abscess and that lesser degree of inflammation can be avoided by adopting my method when necessary; and, as I have said, this is usually the case where the fat is of greater thickness than one inch.

But though mural abscesses are to blame for many ventral hernias, the use of drainage-tubes is equally so. Still, we must sometimes use drainage. I believe I now know how to use them without subjecting the patient to much more risk of future rupture than obtains in a perfectly simple case. I will not enter into a discussion upon the advisability of using drainage. But there are two things against which I wish to protest, viz., the use of irrigating tubes, and the use of every kind of tube for too long a time. My belief is that the dry, the capillary way of draining by means of glass tubes packed with strips of dry bichloride gauze, is the proper one. I cannot too strongly condemn the use of every form of tube, especially double tubes, into which various kinds of solutions are injected. They but tend to break up that tender lymph-tube which so early surrounds our drainage-tube and shuts off our field of drainage from the general peritoneal cavity; or else washing with such tubes disseminates among the intestines the very material which we wish to remove. We should use drainage-tubes not with the object of draining the general peritoneal sac, but to withdraw immediately upon its formation all fluid from a certain locality. We drain locally, not generally. Most of us accept the belief that these drainage-tubes are beneficial within the first three days only; after that time, except in rare cases, the tube has become entirely encysted. It is useless to leave it in longer; yet many prominent men use them for so long a time that the lymph-sac becomes itself the source of a serous discharge. If we withdraw the tube within the first forty-eight hours, the plastic lymph-tube collapses and its walls cohere. If we leave it in for a longer time, the track will probably have to be drained by the daily introduction of a shorter and shorter tube. I would lay it down as a general rule in drained cases, without exceptions, in lean and fat women alike, that the closing sutures shall not include the skin and fat layers; but that the wound shall be treated as I shall describe. By our carefully applied sutures we have succeeded in uniting the peritoneal and muscular and fascial surfaces, except where the drainage-tube passes through them. This latter we remove within two days usually. Treated as I shall describe, this hiatus left in the line of union will become gradually buried under the granulating surface, and will ultimately lie underneath the firm cicatrix of granulation, instead of being a point of weakness in the scar.

It is an undeniable fact that the scar of granulation produced from a fat surface is stronger than the scar of primary union in a similar tissue, inasmuch as firm contracting cicatricial tissue replaces the loose adipose. Furthermore, the scar from granulation contracts in a few months to often less than half the length of the original wound. The time which it takes for such a granulating wound to heal varies, of course, with its size. In four weeks' time a fat surface of six inches in length and two in depth will be closed. The largest I have ever made was eight inches long and five deep: it closed in eight weeks, though a drainage-tube case.

But the increased time under treatment counts as nothing against the certain escape from mural abscess, and a possible subsequent hernia. My patients wear no form of abdominal supporter, as none is necessary.

Method of Operating.—The skin and fat should be cut through smoothly and evenly down to the fascia. All bleeding points are grasped in pressure forceps, or tied, as best suits the fancy of the operator. The fascia and muscle should also be carefully and evenly cut with the knife, and all bleeding arrested by ligature with fine juniper catgut. I am opposed to the use of pressure-forceps here, as they bruise and drag upon the tissues so as to hinder union. The peritoneum is snipped with scissors, and the operation is finished according to the indications. In making the parietal incision, do not search to one side or the other for the linea alba. By so doing we tend to make a ragged wound. Go down straight in the median line through the tissues before you. All I want to insist upon is the clean cut incision and avoidance of crushing the tissues by forceps.

If the operator decides to adopt my method, he will close the wound as follows:

The peritoneum is united by frequent interrupted sutures of catgut, applied in the Lembert manner. Sutures of silk (Czerny) are passed through the fascia and muscle so as accurately to coapt those two layers before the catgut sutures are tied. (See illustration, p. 326). Having inserted the silk sutures, the catgut sutures are tied and the ends cut short. The silk sutures are tied alternately with the catgut, so that they may be supporting all the catgut sutures which have previously been tied. The ends of the silk are left long and all tied together in one bundle, and tucked away at the bottom of the wound. The wound should be irrigated with 1 to 5,000 bichloride solution, and packed with dry bichloride gauze. The procedure is practically the same in all cases, whether or not drainage be used, with the difference that in the latter case we should see that the drainage-tube is long enough to come to the top of the packing, where it can be attended to without soiling the packing. The first dressing is usually made in three or four days, or when the drainage-tube is removed, where used. In that case the track of the tube must be packed with the gauze down to the peritoneum only. The sutures of silk I generally remove on the seventh day; they will be found in the bottom of the wound, usually partly covered by the granulations which have already begun to form.

By using this method in fat women, in drainage cases, and in operations for the cure of ventral hernia, we obtain the following results:

1. Primary union between the muscular and fascial surfaces is insured.
2. Mural abscesses are impossible.
3. The resulting scar is composed of the firmest tissue; it is part and parcel of the scar of primary union between the fascial and muscular edges; it replaces loose adipose tissue and elastic skin; and by its contraction it very much reduces the space through which a rupture may occur.
4. In drainage-tube cases the tube-track is buried entirely beneath a mass of cicatricial tissue, extending from skin to peritoneum.
5. Hernia cannot possibly occur.

EXPERIMENTS ILLUSTRATING THE INFLUENCE OF INTERNAL BATHS IN THE TREATMENT OF TYPHOID FEVER.

By W. E. FOREST, M.D.,

NEW YORK.

In a very interesting article in the MEDICAL RECORD of July 4th, Dr. Beverley Robinson gives his views as to "The Internal Use of Water in the Treatment of Typhoid Fever." Dr. Robinson states that he was led to the position he holds principally by the writings of Dr. Debove and Professor Cantani. Both gentlemen advocate the free use of water internally as a means of reducing temperature and eliminating poison from the system. They use water in this manner in preference to the cold baths externally, accordingly to the Brand method of treatment. Dr. Debove's views, according to Dr. Robinson, are as follows:

"Dr. Debove prescribes no drugs, but he urges his patients to drink water. He gives them six to seven litres in twenty-four hours. Each person passes his urine into a vessel where it is kept, and if the quantity does not seem sufficient to Dr. Debove, he stimulates the zeal of the nurses, and, as he says, he does not simply allow his patients to drink, he obliges them to drink. Dr. Debove concluded that many complications in typhoid fever—if not, indeed, all—are the effect of a poison, and the way of elimination of this poison is through the kidneys. If

cold baths act, perhaps they act in promoting diuresis, for this diuresis is noticed by almost all clinicians."

Professor Cantani's views are much the same, only to the drinking of cold water he adds large injections.

"Professor Cantani, in his treatment of typhoid fever, considers the slight reductions of temperature obtained by drinking cold water as preferable to the marked antipyresis obtained by a cold bath. He adjoins to cold water by the mouth large injections of cold water, rendered slightly antiseptic, by the rectum. The latter he administers twice daily.

"Both of these methods of treatment increase the quantity of urine and diminish its specific gravity, especially the drinking of water, and, as Cantani believes, the antithermic effect is produced more surely than by other hydro therapeutic methods. It likewise seems evident that the cold water is absorbed in large quantities and then cools the entire body, and even the blood. In this manner Cantani considers that the tissues are permeated and cleansed by the water and freed of ptomaines, and this takes place without disturbance of any kind, except occasionally a slight chill. Cantani also believes that if cold injections be employed at the beginning of typhoid fever, it is possible to abort the disease in very many cases."

It will be seen that both gentlemen claim that the most important influence of the internal use of water is its stimulatory effect on the kidneys, and the increased elimination of poison through them.

In this connection it may be of interest to show how greatly the kidneys can be stimulated by what I may call colon baths. The experiments illustrating this were carried out on myself and one other person, a young man in the first stage of acute nephritis.

I first ascertained by a series of observations that the average amount of urine passed between the hours of 9 P.M. and 9 A.M., twelve hours, was twenty-two ounces. Specific gravity averaged 1.016.

Experiment 1.—November 10th, at 10 P.M., after washing out the colon, I injected twenty ounces of milk and water in equal proportions, at a temperature of 110° F., and retained the fluid. Within the next twelve hours passed fifty-six ounces of urine, instead of the usual quantity, namely twenty-two ounces. Specific gravity, 1.010.

Experiment 2.—After flushing of the colon at night, injected and retained sixteen ounces of milk and water. Passed in the next twelve hours fifty-four ounces. Specific gravity, 1.005.

Experiment 3.—Took a thorough colon flushing, but did not retain any of the fluid. Passed during the next twelve hours forty ounces urine. Specific gravity, 1.012.

Experiment 4.—Took no flushing, but at 10 P.M. injected eight ounces of water containing fifteen grains iodide of potash in solution. Awoke out of a sleep in two hours with the peculiar taste of iodide in the throat; this proved that the drug had entered the blood about as quickly as if taken into the stomach. The urine passed at this time, namely, two hours after the injection, gave the reaction for iodide of potash, showing that the drug was already passing out of the system through the kidneys.

The amount of urine passed in the twelve hours in this experiment was only seventeen ounces. This drug, iodide of potash, is supposed to act as a diuretic on the kidneys, *i.e.*, to increase the flow of the urine. It did not do so in this case, and hot water alone proved a much more powerful stimulant to the kidneys.

A large number of experiments were made, all going to prove that a flushing of the colon with hot water, followed by an injection of from a half-pint to a pint of hot water that is retained, is a quick, safe, and powerful means to stimulate the kidneys into action. This method is a more powerful diuretic than any drug known to me. The only precaution to be used in order to retain the hot water is to immediately lie down for a half-hour after receiving the injection. It is a good plan in these cases to be all ready for bed, and to retire immediately after receiving the injection.

The outcome of the experiments made on myself proved, 1st, that from twelve to twenty ounces of warm or hot water can be retained at one time in the colon, and that all of this will be absorbed into the blood; 2d, that the normal amount of urine secreted by the kidneys in twelve hours may be more than doubled by means of such retained injections; 3d, that the mere flushing of the colon by a large quantity of hot water (two quarts at least, at one injection) powerfully stimulates the action of the kidneys. Part of this effect is due to the internal application of heat, and part due to some of the water being absorbed.

This plan of treatment I have found by experience of great benefit in the treatment of all kinds of fevers. Professor Cantani's plan of large cold enemas has not given me the same good results that warm or hot enemas have. As both Debove and Cantani claim that most of the good effect of the internal use of water in fevers is due to the increased elimination through the kidneys, it is fair to assume from the experiments given that a very important auxiliary in these cases to the internal bath by the mouth is the internal hot bath by the colon.

As confirmatory of the views given above, I have the history of a recent mild but well-marked case of typhoid fever, that became free from fever and convalescent in six days under treatment by large quantities of Vichy water by the mouth, and three large warm colon baths each day.

The influence of these colon baths on the first stage of acute nephritis will appear from the following case:

W. C——, twenty-six years of age, clerk, came to my office one morning complaining of the following symptoms: He had a headache, complete loss of appetite, had slept little or none the previous nights, had pain and heaviness in the back, in the region of the kidneys, and, most noticeable of all, he was passing but little urine, this of a very high color, and it caused him pain to pass it. He had had an attack of this kind the previous year, from the effects of which he did not recover in more than a month, so he knew pretty well what the difficulty was. He had brought along a small specimen of the morning's urine for examination. I found, on a chemical examination, about twenty-five per cent. of albumin present; with the microscope, blood-casts and blood-cells in abundance. It was then a clear case of acute congestion and inflammation of the kidneys. I advised his going immediately to bed and to commence the use of the hot colon injections. Owing to business complications he could not give up work for at least twenty-four hours, no matter what the danger might be. I gave him the best and safest drug possible under these circumstances, namely, sulphate of magnesia, a teaspoonful every hour, in water.

The next day he called again. No better—rather worse; had taken the medicine all day, but no effect on kidneys. The water was less, not more than twelve ounces in twenty-four hours, and contained blood in abundance; could be seen plainly with the eye alone. At my suggestion he now went home, took a warm bath, and went to bed. Immediately after his bath he took an enema of a pint of hot water and retained it. In six hours he repeated this enema, and in six hours more took another, same quantity, all retained.

I called at his home the next day, and he gave me the following record as to the amount of urine passed in the preceding twenty-four hours:

12.30 P.M.	4 oz.
4.30 P.M.	6 oz.
7.30 P.M.	4 oz.
10.30 P.M.	5 oz.
11.00 P.M.	4 oz.
7.00 A.M.	9 oz.
10.30 A.M.	5 oz.
12.00 A.M.	3 oz.
Total	40 oz.

That is, during twenty-four hours, without drugs, but under the use of the hot injection, he passed forty ounces.

In the preceding twenty-four hours, while taking a drug hourly, he passed one-third of this quantity. During the last part of the second day he was in bed, which undoubtedly helped to bring about the good result.

The best part of this second day's report was that the pain in the back had almost entirely gone; and I found on examination that the blood had disappeared from the urine and every bad symptom greatly improved. Albumin was still present in small quantity, however. He continued this treatment two days more. The result on the second day of treatment by hot injections was even more striking than on the first day.

He then returned to business, although not entirely recovered, as a little albumin was still found on chemical examination. This disappeared in the course of ten days, and the patient made a perfect recovery.

At the previous attack of this same trouble (not so severe an attack) the patient, under drug treatment, had been confined to the house more than two weeks, and did not entirely recover for a long time after that.

In all cases where the water is to be retained, the colon should first be washed out by a large warm injection.

39½ Washington Square.

THE NEW AMERICANS.

By J. WARREN ACHORN, M.D.,

BOSTON, MASS.

The occasional travelling doctor on an ocean steamship is not a person greatly to be envied. If his title could be stowed with his baggage for the voyage, it would be better for him and equally well for those about him. If sea-sick, he is laughed at by those who are not, and even by some of those who are; the ship's surgeon gives him a wide berth, and the sailors think him a Jonah. If well, aside from the bodily comfort of it, he is no better off. The first day out usually discovers his identity along with the sea-sickness on board, and his mental discomfiture begins. Appealed to on all sides by those who are well in behalf of those who are sick, and by the sick themselves, whose sufferings he would willingly do what he could to alleviate, he can do nothing. The rules of the ship and professional etiquette forbid it. Professionally, at least, he is sadly out of place. Subject to these restrictions I made the home passage recently from Europe. I am never sea-sick. Aside from the usual reading, waiting, and watching the winter waves of the western ocean, I determined to devote some time to a professional study of the "New Americans," as the immigrants on board were styled. Here was a chance to view them in a body, to see what they were made up of physically. They numbered six hundred, and included Italians, Hungarians, Polish and Hungarian Jews, Russians, Bohemians, Sclavonians, and Arabs—practically a village of the varieties that come to us from Eastern and Southern Europe. At first I reviewed them from the promenade-deck, as on sunshiny days they swarmed the main-deck forward and aft, a motley hodgepodge lot. There were young men and women among them, walking quickly and erectly; there were fathers and mothers, with their children, some of whom were plump and ruddy, others poor, puny things; there were women of fifty, men of sixty and even seventy years of age, alone or with others of their kin. I counted sixteen of these old people the day we crossed the Grand Banks. The sea being smoother and the air warmer on that day they showed themselves on deck. There were intelligent faces to be seen among them, and others showing little intellectual force. Dull eyes let little soul-light out of many faces. Meanness and cunning marked many for their own. Expressive lines of care and responsibility had their tracings in the faces and foreheads of some, but for the greater number there was that alone which goes with fear, or sea-sickness, or cold, and the want of proper food and care. The dress of the entire lot was anything to wear, but distinctive, perhaps, of the country that gave the wearer his nativity. There was general lack of neatness in all. The eating, when food was served, was without shadow of refinement. It was animal in the extreme. Cleanliness, if it ever had a thought under the existing conditions, was out of the question. The natures presented varied as much as the nationalities. Spirituality failed to show its head. Pugnacity predominated. I was witness to several rows during the voyage, and on one occasion helped dress the vanquished's wounds. The dusky-skinned Arabs looked strangely un-American. The peculiar physiognomy of certain diseases so pregnant with meaning to the skilled observer was stamped on the upturned faces of many. The ruddy, the anæmic, the jaundiced, the straw-colored, the syphilitic and scrofulous, all looked over the rail together into the sea. There were diseases of the spine and affections of the joints of the lower extremities among them, as evidenced by bent bodies and limping gaits. I have a record of seven that went lame upon the deck, and of eighteen others found to be deformed, six of whom at least showed visible deformity at times through the clothes they wore. Five of these eighteen were children. At the New York inspection these five passed muster, dangling from the backs of their elders. If they had not been packed along in this way they might, perhaps, have been allowed to crawl past the inspector. An old Jewess was pointed out to me by the chief engineer of the ship with the remark: "She has crossed before, and brings the young ones back with her." Six or eight Hungarian Jewesses, girls of seventeen to twenty years of age, were gathered about her. "They are prettier and cleaner than the Russian Jewesses," he continued, "and so preferred."

"Are they intended for New York houses?" I asked. "Yes, or for the Hungarian miners in Pennsylvania. This old woman has crossed with us before—a regular business with her."

Later in the voyage, with the knowledge of the captain and the tacit consent of the ship's surgeon, I began the self-imposed task of making a physical examination of these immigrants — nautically speaking, a professional overhauling. This was done in the between-decks of the ship. A part of what I gathered, however, was afforded me in connection with the surgeon's office. An examination of one hundred and fifty three selected cases out of the six hundred on board, ninety of whom were males and the balance females and children of either sex, discovered the following: Four cases of advanced consumption, all men, one of whom died on the voyage and was buried at sea. The ship's surgeon admitted my record of four by saying, "Yes, there are four, and probably more." The sallow complexion of inherited syphilis, with the peculiar notched teeth, was noted in six. Two cases of strumous fetid abscess among the men underwent treatment at the doctor's hands during the first week out. I was present at both operations. The suppurating glands were in the left neck in the first instance, and in the groin, same side, in the second. I do not know that these men were stripped and examined in New York. It was not done in my sight. They were both suffering from a constitutionally "loathsome disease," and officials, as the law provides, should effectively debar any such from landing in this country. It should be borne in mind that both these men wore clothes, had vaccinating cards, and could walk. Three men under the doctor's care were affected with a local venereal disease more or less chronic, and incurable in the short time afforded for treatment. An Arab suffering from inflammation of the stomach was among the sick. The day we were due in port he was at one time unconscious from pain and weakness, but revived sufficiently to land. Before we left the dock in Europe he was on the sick list and begging for treatment. He was brought to me by a gentleman on board who understood

his language and wants, and who knew that I was a physician. One case of scarlet fever or measles subsided before it was called into account. I did not see this case; it was that of a child, but the probable outcome of the same was discussed in my presence. A mother gave birth to a child in the water closet. She was discovered there as she was in the act of disposing of her babe. There was a case of delirium tremens in a man of thirty-five. His wife had died in the old country, but his six little children attended him. They were all of dependent age. During twelve days the man was straight-jacketed, and it was an open question with the surgeon whether he would die, or living, be sobered up sufficiently to land. Big doses of bromide, chloral, and capsicum finally tided him by the inspectors, into the United States of America. I have notes of nine strumous or rickety children. One of these, having an abscess pointing in the right neck, was operated upon. Another died and was buried at sea. One young man was found suffering from cramps in the lower extremities, due to some, to me unknown, central cause. They were liable to occur at any time, he said, and while they lasted he was unable to walk or help himself. Valvular heart disease in a woman of thirty allowed her to move along the deck, but the effort of mounting a flight of steps visibly exhausted her for the time. A young man among the sailors was pointed out to me by the surgeon as likely to be returned. He was blind in his left eye from cataract due to syphilis. He was returned. More than ten pairs of hands out of three hundred held up showed permanent injury or deformity of some sort in one or both. The noticeable foot deformity was that of enlargement of the second joint of the great toe, the latter turning sharply out. This is due, probably, to the peculiar pointed shoe worn so extensively in Europe by the laboring classes. The "ploughman's shoe" it is styled, and at best it is an ugly affair. Of skin diseases, parasitical or otherwise, there were any number. One of the saloon passengers, a Jewess, having a berth in the after-cabin, and a seat at the captain's table, because of her scratching and by the surgeon's advice, was let down from her high estate to the main-deck, in spite of her protests and the fact that she wore diamonds. I shall mention but one other skin disease, that of favus of the scalp. According to Bulkley, of New York, this disease is pathognomonic of Austro-Hungary. The baldness resulting is usually permanent. Two Italians, numbers 61 and 187, were rare specimens from the mountainous wilds of that far-famed country. I remember having seen but one other such, and that while serving as interne in the Brooklyn Hospital. The original was haired up to his diaphragm like a black dog. None of the Italians in the wards could well understand him, and when he left the institution, it was of his own free-will, knife in hand, through the hospital kitchen and over the yard fence by the jail. Of those who went lame on the deck three were old men, and their disability was found, on examination, to be due in each case to ulcer of the leg; difficult enough to cure in workingmen of advanced years. There were seventeen old men and women in all on board, as I rated them, good hospital subjects—men and women too old to forget the old country, too old ever to learn to love or work successfully in the new—practically, unless otherwise provided for, turned loose in America to beg—beg during the summer months in the country places, and spend their winters in the various hotel hospitals of our larger cities, having gained a freight-train ride to town. Any man who has ever served in the hospitals of our larger cities, particularly those in and around New York, can tell all about the fall "round ups" and of the return of the wanderers to winter quarters. Statistics show that fully one-half of the inmates of our seaboard city hospitals are foreign born. Save the man with the cataract, I saw but one other person of the entire six hundred detained by the inspector at New York. He was a lonesome, ratty-looking, little old man of seventy. He appeared astonished with the liberty taken with his person, and shook his vaccinating card in the face of the man who turned him round, defiantly. As he stood this review without falling, he was passed. The red vaccinating card saved him, with the others, for citizenship in the United States.

Such this village of six hundred presented itself, and such is the record in part of the physical condition of the one hundred and fifty-three who underwent examination. One question for us is, What became of these immigrants after they landed? I have already indicated the probable destination of the old men and women, and the Hungarian Jewesses. The fifty Hungarians and Poles, with their consorts, could probably be found among the recently mining rioters in Pennsylvania; or if not, then upon some railroad dump, at work, since the Irishman has graduated from that position and taken up with the better government of our cities. Of the one hundred Italians, some of them, perhaps, located in New Orleans and enjoyed the late festivities indulged in by that town; and some of them, doubtless, might be found here in our Northern cities, selling shoe-strings or bone buttons on the street corners. The Russians, of course, are employed as "sweaters" in the New York slums, making pants at thirteen cents a pair. The Germans and Scandinavians are probably located on the farming lands of Minnesota or of the Dakotas. The Arabs and Sclavonians numbered about twenty-five. What they expect to do with themselves in this country is more than I can divine. Drive camels, may be, on the Great American Desert. The balance of the lot were mainly children and young women, of whom there were very many. These latter presumably find employment among us as servants. This disposes of the cargo for the most part, and what an addition they are to our numbers! How does this imported village compare, do you think, with an old-time New-England village of six hundred souls? In numbers, at least, there is equality, but how is it, if we attempt to measure sterling qualities, intelligence, refinement, worth? Will one of their genus ever develop into the time-honored country squire? Think you that one of these Sclavonians will transmute into the village parson? I failed to see the school-master's face among them; the blacksmith's, even, was wanting. The man that kept the corner grocery, whose red shutters used to creak on snowy nights in the night wind, I failed to see him; or the doctor, whom the people were wont to love and trust; or the postmaster, versed in the politics of the State and town. The rich man may have been among them, but I didn't see him. I didn't see even the town clown. And the farming people that lived in the surrounding country, I am not sure that I saw them there.

The captain of our ship remarked to me one day, that we had more paupers in America than in any other country abroad. "If this is so, captain," I replied, "is it any wonder, when your ships bring us four thousand such as these you have here every month? It's a pretty good country that can absorb the scum of all nations, and none can hope to do it profitably." That we are the laughing-stock of all nations, because of this acceptance and our indifference, is true. The conversation continued on the subject of immigration. The mate of the ship told the following story: It appears that Carver's Wild West Show took passage on the ship on her previous eastern voyage, and that a part of the paraphernalia of the same was an old-fashioned stage-coach. This was stowed between decks, and was used by the cow-boys of the show as a sort of rendezvous. Here they used to play poker daily. Under the driver's seat in this coach a little nigger boy had stowed himself away. Three days sufficed to starve him out, and when the mate discovered him and demanded to know what he was doing there, the Ebony replied: "I'se only want ter black der cow-boys' shoes, sar."

On arrival of the ship in a German port, the little darkey made his escape, and the captain and the mate were held in the sum of three hundred marks by the offi

cials for the discovery and return to America of this little, sound nigger, who had escaped into all Europe. If we were to impose a tax of three hundred marks on every head escaping into this country, we should doubtless have less paupers and more prosperity. If we were to establish a standard of immigration and insist upon certain qualifications of admission into our land, greater respect would be entertained for the privileges of our citizenship. If we are to have no intellectual property, or moral qualifications as terms of admission, or if they are to become a dead letter, at least we should demand that the people who come among us be physically sound. If this shipload is a fair sample, then the amount of disease that is being imported annually into this country is appalling. If our law-makers are so indifferent to this question that they will make no adequate provision for the well-being of the nation, it is time for the physicians of America to unite in demanding as a plank in the next presidential platforms that at least only sound immigrants be landed here. Some effort should be made to preserve the standard of health among us as a people. At present sufficient care is not exercised. Every man, woman, and child seeking a home here should be stripped and examined by competent men. Whether this work can best be done here or abroad is not for me to discuss. A vaccinating card should not be received as a passport to American citizenship, to privileges and prerogatives sought for by all men in all ages. If the American people are to have a lasting future, they must see to it that the seeds of disease are no longer allowed to be sown broadcast in the land.

I have not told all that my note-book contains, but I have cited enough to show that the present system of examining immigrants admitted into the United States is ridiculously inadequate. It is time this grave national question received proper attention. It is time that the hordes dumped daily upon our wharves, to scatter at will, if they are to be judged by no other standard should at least bear the trade-mark, "physically sound."

Clinical Department.

PAPILLOMA OF THE OVARY (DOUBLE) DISSEMINATED EXTENSIVELY OVER THE PERITONEUM—OPERATION—RECOVERY.

By FRANK L. BURT, M.D.,

BOSTON, MASS.

On making abdominal section for the removal of any growth, few conditions are found more painful to the operator and serious to the patient than the discovery of portions of papillary masses disseminated over the peritoneum.

A short time since, such cases were given up for good, and it was not even expected that they would recover from the operation. Recent experience of specialists has proven, however, that such is not the case, and that diffused papillomata are not of necessity malignant. They may entirely disappear, and we now have recorded cases of perfect recovery. Such has been the outcome in one of my own cases, the history of which is as follows:

Miss D——, aged thirty-three, was first seen by me in March, 1890. To describe briefly: Her menses appeared at fifteen, always regular, of three or four days' duration, and always associated with severe pain. During the last four years her pains were never any worse, but at times she was even better. Has had irritation of the bladder frequently for two years past. Bowels always constipated, but very much worse for last two years. Except for painful menstruation and sick headache she has considered herself well until about four years ago, when she began to feel pain in the right ovarian region on reaching or stepping up. She could not lie on the right side. She experienced a fulness after eating a very small quantity. About a year and a half ago the abdomen began to enlarge with an accumulation of ascitic fluid. Six months later her physician was consulted and a diagnosis made of "gas and water" in the bowels. The treatment was turpentine, blue pill, etc.

In November, 1889, Dr. Mary Carleton was consulted, and a diagnosis of ovarian tumors was made. The patient was referred to me for operation.

Between November and the following March, when I first saw her, she took about seventy-five vapor baths. These reduced the ascitic fluid somewhat, and, as a consequence, made her feel better.

In March I diagnosed ovarian tumors and advised removal. The patient entered my private hospital April 20, 1890, and was operated upon the same day in the presence of six physicians. On opening the peritoneum about two quarts of fluid escaped. On the right side was found a cyst, a little larger than an infant head, which proved to be a papilloma with contents partly fluid. A similar growth, of about half the size and entirely exposed, was seen to arise from the left ovary. The growth had so thoroughly come in contact with the omentum and bowels that these organs were studded with thousands of these papillary masses from contact with the primary growth. The omentum was considerably thickened, and both omentum and bowel presented a very congested, angry appearance. These conditions were considered by all present to make the case an utterly hopeless one for recovery. The growths were removed in the usual manner, and I was able to make a stump in tissues nearly free from any appearance of the disease.

The cavity was thoroughly washed out with boiled water to get rid of as much *débris* as possible. Numerous small pieces were washed away. The wound was closed over a very small rubber drainage tube, which was kept in place for forty-eight hours. After putting to bed we had a mishap in the way of an extensive burn on the right thigh from a water bag. This was several weeks in healing, and did not present a healthy appearance considerable of the time; but aside from the fact that it delayed recovery I cannot but feel that it was beneficial to the patient. I do not, however, under similar circumstances, recommend quite so extensive a counter irritation if indicated at all. Nothing else of interest happened while under my care for a period of four months. On her anniversary day she presented herself, and everything was very satisfactory. There was a gain of over twenty pounds in weight, and nothing was found about the abdomen by way of new growth, accumulation of fluid, or tenderness, and now, after a period of fourteen months, presenting a picture of health, we can consider the patient as cured. She was seen recently by her physician, Dr. Carleton, who describes her as being in perfect health. Constipation, from which she has suffered so long, has been improving rapidly during the last few months.

Outside of my own practice I have seen two cases. One was of double ovarian papilloma, of long duration, and with an excessive amount of fluid. Operation brought relief in every way, but the patient died from exhaustion after a very short period.

The other was of shorter duration, in which the disease arose from the left ovary. There was little previous history, and nothing after operation, as the patient was said to have died of septicæmia within a few days.

Concerning this class of cases there is but little literature of which I am aware. In the *Boston Medical and Surgical Journal* for 1874, Dr. H. O. Marcy, of Boston, reported a case, which shortly proved fatal from sepsis. In the same year Dr. John Homans also published a case in the same journal, which alike resulted fatally. Dr. Flaischlen published a monograph in the 1889 volume of the *Zeitschrift fur Geburtshulfe* of the collected literature on the subject. He found six cases, including the two above mentioned, published in Boston in 1874.

In the *Centralblat f. Gynak.*, June 7, 1890, Dr. Seetu-

gin related two cases. In one case a partial removal of a papillomatous ovary was followed by apparent disappearance of a large mass which infected the peritoneum. There was marked ascites, but it did not recur. In the second there was disease of both ovaries, with ascites and infection of the peritoneum. The right ovary only could be removed. It was papillomatous, and also bore signs of malignant degeneration. The patient was living a year later, having no recurrence of the ascites, and the tumor from the left ovary grew but little. The peritoneal papillomata had apparently disappeared. The patient later became insane and the future history could not be traced.

Professor Freund has found that even a partial removal of these papillomatous tumors of the ovary may be followed by atrophy of the disseminated growths.

Other articles on this subject are by Dawson in the *American Journal of Obstetrics*, vol. xvii., p. 855, and by Coblenz in the *Archives for Pathological Anatomy*, 1880, vol. lxxxii., pages 268–316.

In the present year there was a report of a case of papilloma of the Fallopian tube by Dr. Doleris.[1] He thinks it the first case noted in France.

Concerning this class of cases it seems necessary for the profession to hold different views from those entertained even so short a time as two years ago. New light has come to this subject, and we find that we need not of necessity feel alarmed when one of our patients is afflicted in this manner. We should remove the growth complete, if possible; but if that cannot be done we may know that the remainder may be taken care of as stated above, and the case recover. An early operation is quite generally advised in cases of ovarian tumors at present, and in this class I think an early operation especially to be recommended before the patient begins to reduce much in health. It has been a surprise to us that these disseminated masses could be in any way controlled so that their growth should be stopped and cause no further harm to the body.

There is no explanation at present of which I am aware, and we must leave this point for future investigators to explain.

751 Tremont Street.

Progress of Medical Science.

Modern Renal Surgery.—Dr. A. Obalinski sums up his views regarding the treatment of severe inflammatory affections of the kidneys and their sequelæ in the following way: 1. Suppurative inflammation of the kidney and surrounding structures indicates the operation of nephrectomy in order that free exit may be given to the purulent and other inflammatory excretions, and that the focus of the disease may be thoroughly cleansed, and further extension of the suppuration to important parts, as, for example, the thoracic and abdominal cavities and the hip-joint, be thus prevented. In most cases the single lumbar incision, as was performed by Simon, will suffice, but when there has been extensive undermining of the peritoneum the formation of a large flap, as practised by Bardenheuer, is to be preferred, as such operation permits of ready access to all extensions of the main pus-containing cavity. 2. Ureteral fistula should always be treated by removal of the corresponding kidney, provided the surgeon can assure himself of the existence of a sound renal organ on the other side. Nephrectomy in such cases is indicated, not only on subjective grounds and when, for instance, the external flow of urine cannot be restrained by any apparatus and the patient is thus prevented from following his occupation and from enjoying a comfortable existence, but also on objective grounds, since, notwithstanding the utmost precautions, an old ureteral fistula may result in suppurative inflammation of the corresponding kidney and of the adjacent soft parts. 3. Nephrectomy performed under these last-mentioned conditions offers much less favorable prospects than in cases in which there is an absence of suppuration or of cicatricial adhesions. 4. There can be no doubt that, under equally favorable conditions, the transperitoneal method can be performed more rapidly and with greater ease than the extraperitoneal method of nephrectomy, and that the progress toward recovery is more speedy after the former operation. The transperitoneal method, however, is not applicable to every case, and should be reserved for those instances in which the mischief is confined within the capsule of the kidney, the extraperitoneal method being indicated when the suppurative process has involved the perirenal structures.—*Volkmann's Sammlung Klinische Vorträge.*

Syphilitic Disease of the Lungs.—Dr. Haslund distinguishes two forms of pulmonary syphilitic disease: 1. The diffuse form—an increase of the interstitial connective tissue. The affection always begins at the root of the lung and extends thence. 2. The gummatous form—one or many gummata scattered through the lung, except the apex, which is rarely affected. Both forms often coexist. The course of the disease is sometimes very rapid, death occurring in from two to six months. In other cases the disease causes no symptoms, and the presence of pulmonary disease may be discovered only at the autopsy. In the early stages there are no physical signs; later on, in some cases, dulness on percussion over the root of the lung is noticed, and inspiration becomes rough and sharp. Toward the end respiration acquires a cavernous character. Syphilitic lung disease is difficult to diagnosticate during life. The distinction from phthisis is difficult. The diagnostic points on which Professor Haslund relies are: 1. Absence of tubercle bacilli. 2. Localization; the apex is rarely affected in syphilis, almost always in tuberculosis. 3. The downward progress of the case is much more rapid in syphilis without appropriate treatment than in phthisis. 4. Absence of fever in the earlier part of the disease. 5. History of syphilis. 6. Results of antisyphilitic treatment. The prognosis is good if suitable treatment (mercury and iodide of potassium) be adopted in time. The disease is rare. Professor Haslund has, however, diagnosticated and successfully treated several cases.

Essential Spasm of the Cardiac Orifice of the Stomach.—Dr. Stefano Mircoli, in speaking of spasm of the cardiac orifice of the stomach, points out that the symptom is due not to stimulation, but to the want of it, since, if the vagus is divided the opening remains closed, unless the peripheral end of the cut nerve is artificially stimulated (*The British Medical Journal*). Schiff has shown that there is a special twig from the vagus which regulates the opening of the cardia. The cardia is richer in ganglia than the stomach itself, there being twelve in the former and only ten in the latter; this richness in nervous material almost entitles it to be called the "brain" of the stomach. The different parts of the cardiac orifice are functionally independent of each other, and one-half may be in a state of contraction while the other is relaxed. Mircoli relates three cases with the object of showing that in some persons, otherwise perfectly healthy, the susceptibility of the cardia to nervous impressions may be so marked as to amount to disease, and may be inherited as a diathesis. The first case was that of a man, aged fifty, who, in May, 1885, suffered from melæna; the bleeding recurred several times, and the patient died of exhaustion in the following September. Among other symptoms, intermittent spasm of the cardiac orifice was observed; when the patient was most weakened by loss of blood solid food did not reach the stomach, and even liquids partially failed to enter it. On passing a bougie, the œsophagus was found to be unobstructed, but firm resistance was encountered at the cardiac orifice; this sometimes yielded, but at other times could not be overcome. The constriction always vanished spontaneously in a few days. A son of this patient, aged twenty-four, went to bed one night in 1888 after a hearty supper; in

[1] Bull. de la Soc. Obstet. et Gynec. de Paris, January, 1891.

the morning he could not swallow, everything taken, whether solid or liquid, being stopped at a point corresponding to the cardia, and then thrown up. The spasm began to yield after some hours to energetic counter-irritation over the epigastrium and inunction with oil of hyoscyamus, and finally disappeared on the following day. A brother of this patient, aged twenty-seven, suffered from similar symptoms in 1890, under the mental stress caused by an impending lawsuit; the condition persisted more or less for more than a month, and finally ceased when he had won his case. Mircoli thinks that in persons of neurotic temperament such a condition might, by frequent repetition, lead to true stenosis of the cardiac orifice, and he quotes a private letter received by him in 1885, from the late Professor Loreta, in which that distinguished surgeon says: "Of the nine divulsions which I have performed for stenosis of the cardiac orifice, three were caused by contraction with subsequent fibrous degeneration. In the history of these patients (all of whom were women) hysteria was a prominent element; this was accompanied by dyspeptic phenomena, at first intermittent, but after some years becoming continuous and so preponderant as to induce agonies of hunger and thirst. There was no cause or circumstance which could lead one to conjecture sclerosis or cicatricial contraction. This is a chapter of pathology which requires to be illustrated and extended, so that medical practitioners may be forewarned against catarrhs, gastritis, cancer, etc., diseases which sometimes are merely secondary to purely mechanical conditions."

A Reliable Purgative Enema.—Dr. Charles P. Noble writes, in the *Medical News*, that the following enema has proved so reliable and satisfactory in his hands that he feels it is worthy of a brief note:

℞. Sulphate of magnesia ..... ℥ij.
Glycerine ..... ℥ij.
Oil of turpentine ..... ℥ss.
Water ..... ℥ij.
M. Label: "To be used as an enema."

To move the bowels after abdominal section, or after plastic operations on the female pelvic organs, it has been in constant use for many months. When used alone it has moved the bowels, as a rule, promptly, and has been equally effective when given as an adjuvant to some cathartic taken by the mouth. Prior to the employment of this formula I had used the simple enemata of glycerine, and of glycerine and turpentine, which are distinctly inferior to the one above recommended. The combined action of Epsom salts, turpentine, and glycerine is very effectual, not only in evacuating the rectum, but also in getting rid of flatus, which is the cause of much of the pain present after abdominal section. I have had the opportunity, upon two occasions, of testing the activity of this enema in cases of threatened obstruction of the bowels following operation. Other measures failing—including purgatives and large and small enemata—I have introduced a long, soft, tube up the rectum, and given this enema into the descending colon, with the happiest results. Now that the use of opium has been banished from the after-treatment of cases of abdominal section, this enema has, in my hand, become the great anodyne. When given through the rectal tube its employment promises much in cases of partial obstruction of the bowels, also in obstruction due to paralysis of the bowel. The enema is best given through a hard rubber piston-syringe.

Physiology of the Gastric Glands.—According to Heidenhain, the delomorphous or parietal cells of the gastric glands—that is, the glands of the fundus—secrete or elaborate the hydrochloric acid of the gastric juice, while the adelomorphous or central cells secrete the pepsin. One of the chief arguments advanced in favor of this view rests on the experiments of Swiecicki, who asserted that in the œsophageal glands of the frog pepsin alone is formed, while only hydrochloric acid is formed in the stomach. Fränkel has submitted the statements of Swiecicki to a renewed test. He prepared the mucous membrane of (1) the œsophagus, and (2) the fundus of the stomach of ten frogs, and extracted each separately in two litres of water. To 18 c.c. of the watery extract of each there was added 2 c.c. of a one per cent. dilution of hydrochloric acid, and a small piece of fibrin. Both mixtures were kept at 37° C. for twenty-four hours; both extracts digested the fibrin. It would seem, therefore, that both the œsophagus and stomach of the frog contain pepsin, or rather, pepsinogen. This would tend to show that in the frog the delomorphous cells secrete both pepsin and acid, for fibrin is digested in the stomach when the secretion from the œsophagus is prevented from entering that organ. Fränkel found that the mucous membrane both of the stomach and œsophagus produced a mineral acid, for both gave the phloro glucin-vanillin reaction. Contejean finds that section of the vagi does not interfere with gastric digestion in the frog. Electrical stimulation of the peripheral end of the vagus, or of the central ends of the vagus or glosso-pharyngeal, causes a copious secretion of mucus. In the last case there is no secretion of mucus when the vagi are divided. Perhaps the result is due to a reflex secretion, the reflex centre being in the bulb, while the vagus is the efferent channel for the impulses affecting the secretory glands. In birds also it would appear that the vagus influences the secretion of the gastric juice. Oxenfeld finds that in birds (pigeons) stimulation of the peripheral end of the vagus is followed by a copious secretion of acid gastric juice. At the same time the stomach is forcibly contracted, and it might be assumed that the increased quantity of gastric juice was simply forced out of the glands by the concentration of the musculature of the stomach. Oxenfeld, however, is of opinion that this is not the true explanation, and he assumes that the vagus contains secretory fibres for the gastric glands.—*The British Medical Journal.*

Epidemic Jaundice.—Dr. Arthur Henning believes this disease to be caused by a specific virus. He has observed several outbreaks of it. In one family a healthy little boy of two and a half years fell sick, with the symptoms of slight gastro-duodenal catarrh. The liver was somewhat enlarged; he was restless and easily tired, and there were signs of some inflammation of the kidneys; jaundice was present. In a few days the general condition got better, but the yellowness of the skin and the pale color of the fæces continued some time longer. Enlargement of the spleen was now noticed. All these phenomena, however, disappeared after several days. Ten days afterward a little sister, aged three and a half years, was attacked by a similar train of symptoms, only in a more severe degree. She suffered from violent delirium and intense headache. Some days later a child three years of age, who lived on the next floor below, was seized with a similar illness; then the brother of the last-mentioned child, aged five years, became ill; and finally the parents of the first-mentioned two children—the illness in the mother's case brought on abortion. Details are given of several similar outbreaks of jaundice—*e.g.*, in one family mother, servant, and five children attacked, only the father and one child remaining healthy. A few deaths have been caused by this disease; it is especially dangerous in pregnancy and the puerperal state. Dr. Henning believes the epidemics he has observed in Königsberg are caused by the bad water of that town. He considers the malady to be a general disease affecting the whole organism, caused by a specific virus akin perhaps to the virus of malaria. The virus multiplies outside the body, and infects one or more persons at the same time, but is not transferred from patient to patient—*i.e.*, the disease is not contagious. It is to be distinguished from simple catarrhal jaundice, and from jaundice from obstruction, which are merely local diseases. For treatment he recommends large doses of calomel and muriatic acid, and irrigation of the large intestine; the diet should contain as little fat as possible.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 19, 1891.

MOSQUITOES AS PREVENTIVE INOCULATORS.

WE referred recently to the curious method of conferring immunity against yellow fever employed by Dr. Carlos Finlay, of Havana, namely, causing healthy individuals to be stung by mosquitoes which had previously bitten those suffering from the fever. The experiments in this direction have been carried on now for about ten years, and the results would seem to show that this insect is a good attenuator of the yellow fever virus.

In the *American Journal of the Medical Sciences* for September, 1891, Dr. Finlay presents some statistics of his preventive inoculations by means of these insects which are interesting. He was fortunately able to obtain some useful comparative statistics from the fact that he had medical charge of two religious communities, the members of which are partially renewed almost every year by the arrival of new-comers from Spain to substitute others who have resided several years in Havana. Nearly every year he inoculated some of the new-comers, while others did not go through that ordeal. During the period 1883–1890, forty-nine of these new-comers were inoculated, and thirty-two were not. After deducting from the inoculated thirteen cases who had not been long enough in the country to permit any definite conclusion to be drawn from them, there remained thirty-three inoculated, and thirty-two not inoculated members of the same communities, having arrived in the same years, leading the same life, and exposed to the same chances of infection. Indeed, it would be difficult to find anywhere a better opportunity for comparing the results of any method of prophylaxis. Of the inoculated some had no febrile symptoms, either immediately after the inoculation or subsequently; others had a mild attack of fever, accompanied or not with albuminuria; and two had regular yellow fever, from which they recovered. Of the not inoculated, twenty-one either had a mild fever or escaped all illness, and eleven had yellow fever, five of them dying. Thus none of the inoculated died of yellow fever, whereas five (or fifteen and a half per cent.) of the non-inoculated did die of it. Of all the persons inoculated in and out of these communities, but one died of yellow fever.

From a study of these comparative results, and of the results obtained in other cases in which inoculations were practised by Drs. Finlay and Delgado, the author draws the following conclusions as to the value of his method:

1. The inoculations with one or two recently contaminated mosquitoes, in the manner practised, are free from danger, inasmuch as the numerous trials which have been made have produced at most (in about eighteen per cent. of our cases) a mild attack followed by immunity.

2. We must attribute to the influence of the inoculations with contaminated mosquitoes: *a*, The mild acclimation observed in ninety-four per cent. of our cases, whereas the same desirable result has only occurred, *cæteris paribus*, in sixty-five and a half per cent. of the non-inoculated; *b*, the reduction of cases of regular yellow fever to the proportion of six per cent. instead of nineteen per cent., and, *c*, that of fatal yellow fever to less than two per cent. instead of fifteen and a half per cent., one single death from yellow fever having occurred among the sixty-seven persons inoculated since 1881 until the present date.

3. The contaminated mosquitoes appear to lose, either partially or completely, their contamination after they have stung healthy subjects; whereas the contamination appears to become intensified by successive stings of the same insect on yellow fever patients.

4. The inoculations performed during the colder season should not be considered to afford sufficient protection, but should be repeated on the approach of the hot season.

INTOXICATED PHYSICIANS AND THE LAWS CONCERNING THEM.

HARD-drinking physicians, if there are any such in Georgia, will now have a disagreeable time of it, as a statute has been passed by the legislature of that State disqualifying any medical man from further practice who has once been convicted of drunkenness, and imposing a heavy penalty upon the man thus disqualified if he attempts to practise medicine again. It may not be known that we have also a law in New York on this subject, but it concerns itself with the drinking physician only in case he does harm to a patient while intoxicated, and he can otherwise drink as much as he likes, being subject only to the laws governing all citizens of whatever calling. The following is the New York statute: "A physician or surgeon, or person practising as such, who, being in a state of intoxication, administers any poison, drug, or medicine, or does any other act as a physician or surgeon to another person, by which the life of the latter is endangered or his health seriously affected, is guilty of a misdemeanor." Another section declares that if, under like circumstances, the patient's death results, the physician is guilty of manslaughter. The penalty imposed by the Georgians upon a drunken physician may perhaps not be too severe, but the passage of such a law by the legislature is in the nature of a deliberate insult to the physicians of that State.

SCIENTISTS AND MIND-READING.

IT may be interesting to learn that another distinguished exponent of the exact sciences, Professor Oliver J. Lodge, has gone over in a manner to occultism. Professor Lodge was president of the Mathematical and Physical Science Section of the British Association. He is

one of the foremost of English physicists; but he thinks there is something in telepathy. He says:

"Is it possible that an idea can be transferred from one person to another by a process such as we have not yet grown accustomed to, and know practically nothing about? In this case I have evidence, I assert that I have seen it done, and am perfectly convinced of the fact. Many others are satisfied of the truth of it, too. Why must we speak of it with bated breath, as of a thing of which we are ashamed?"

There is, we venture to say, no reason to be ashamed of the belief, but only of the reasons for holding it. The trouble has always been that telepathy cannot be demonstrated under such rigid conditions as to exclude all possible error. There are people who seem to think that by accumulating an enormous number of ghost stories one may finally prove that there are ghosts. But, in fact, what we want is simply one genuine ghost; then science will be satisfied. So with "telepathy."

ENFORCING SANITARY MEASURES ON STEAMSHIPS.

The steamship companies carrying steerage passengers to this port have been notified by the Treasury Department that the Act of Congress, requiring a "certain allowance of cubic air-space" to each of these passengers, will hereafter be rigidly enforced, and the penalty provided for its violation will be inflicted.

It is time that something was done in the way of looking after the health of our future citizens, and forcing the conscienceless steamship companies to do as they are told. The English authorities do not enforce their own passenger act, perhaps because they are not concerned with the future of the emigrants that leave or pass through their country and seek a home in ours. In a letter on "Ship Sanitation," addressed to the United States Special Commission on Emigration, Dr. C. H. Leet cites many cases of deliberate violation, by two of the transatlantic lines, of even the simplest rules of hygiene, let alone the very reasonable sanitary requirements of the emigration laws of this country, and of the passenger acts of Great Britain. Furthermore, he shows how the managers of the companies referred to gag their surgeons and forbid them to give any information concerning sanitary matters on shipboard to the officers of the Board of Trade at Liverpool. Dr. Leet served as ship's surgeon for a number of years on the steamers of two lines running between this port and Liverpool, and is well known to many physicians in New York. He seems at first to have tried to shut his eyes to some of the more common abuses, knowing that his protests would be unheeded, and that he would be put ashore. But the evils became so great, and the disregard of the health not only of the steerage passengers, but of the ship's crew as well, became so brutal, that he was forced to cry out against it, and in crying lost his berth.

The evil, instead of growing less, has been getting worse, and this law concerning the allowance of air-space for each steerage passenger is persistently ignored by most of the Atlantic steamship companies. Many of them indeed crowd the passengers under decks in a way that they would not be allowed to crowd cattle. In the steerage of some of the ships that have come here this year there has been a disgraceful condition of things, which the officers of the ships were powerless to change, as they had to take all the passengers who were sent aboard, and had to dispose of them when once in the ship as best they could.

The only way these companies can be made to obey our laws is to enforce the penalties for disobedience. They are now much more careful than they were as to the class of passengers they take, knowing that they will have to carry back at their own expense all those whom our laws will not allow to land; and if we make them suffer in pocket for disregarding our sanitary regulations, they will be among the most active in seeing that these are strictly enforced.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

The meeting of this Congress, which takes place in Washington next week, gives every promise of being very successful.

The completed programme, which has just been received, shows that fourteen special national associations will unite in scientific work and social enjoyment.

The general sessions of the Congress will be held in the afternoon, leaving the morning and evening for the work of the special associations. As between one hundred and fifty and two hundred papers are promised, it is evident that the quantity of work will at least be satisfactory.

THE STATE CHARITIES AID ASSOCIATION.

The annual report of the State Charities Aid Association for the year 1890 contains many facts that are interesting to medical men, for the Association's field of work is as wide as it is beneficent in character. Much stress is laid naturally upon the success obtained last winter in passing a law which puts all the pauper insane in State institutions and under the care of State officials. By this law over two thousand insane, who had previously been confined in county poor-houses, will be placed in State hospitals under competent medical care. We regret to learn that there is expected to be an organized effort next winter to repeal or amend the law in question.

The Association is trying to secure a much-needed reform in the care of pauper and indigent epileptics and idiots.

For the former class it is proposed to establish a colony somewhat on the plan of that at Bielefeld, Hanover, and consisting of a farm, small buildings, larger buildings, a hospital, school-house, work-shops, farm buildings, and laboratory. There are already three hundred and thirty-four epileptics in the State's county poor-houses who would form a nucleus for such an establishment. As we have already pointed out, such a colony would certainly fill a very great want in the community. The question arises, however, whether the State ought to undertake the care of a certain class of sick persons who are not, like the insane and idiotic, legally its wards. The committee having the subject of hospitals in charge recommend separate custodial institutions for the unteachable and adult idiots. It is recommended also that

the different counties provide small cottage hospitals in the larger towns for the care of the pauper sick. At present such cases are as a rule miserably provided for in the poor-houses.

In reading over the report of the Association one cannot but be impressed with the enormous amount of intelligent and voluntary work done by its members. Too much credit can hardly be given for what has already been accomplished. It is a pleasure to find also that medical men hold so prominent a place numerically and otherwise in the membership.

THE ESSENTIAL, THE LIBERAL, AND THE TECHNICAL.

The season is at hand when a good many physicians and their friends are debating whether the boy shall go to college or to a technical school, or shall go at once into business. To those who have children ambitious to enter a profession, the college problem is a serious one, for it means several years more of expense and several years delay in the help which the parent expects from his sons. There is still such a difference of opinion also as to what is really the best kind of preliminary education for medical students, that an article entitled "An Attempt to Determine the Ideal Preparatory Course of Studies for the Learned Professions," by Dr. Charles McIntire, naturally excites a special interest. Dr. McIntire, however, does not pretend to have solved the problem. He devotes himself chiefly to collecting the opinions of educational experts on the subject.

It is admitted that in educating a youth he must learn the "essentials" at school, liberal studies and those which train the mind at college, special and technical studies at the university. The mooted question is now, how to get in the liberal studies without making education too prolonged or too costly. The importance of such studies is universally admitted. The young man who passes from the "essentials" taught at school to the special and technical studies taught at the medical college is never really educated except through extra and special efforts of his own. The measures suggested for making a college course feasible to the medical student are: earlier preparation for college and special courses in the last year or two, by which the medical course can be shortened. It is possible also in many colleges for students to go through the four years' course in three years. In various ways it is, therefore, now being made more practicable for young men to graduate from liberal colleges at the age of twenty or twenty-one, with a year's work done on their medical course.

There is an increasing popularity of late years accruing to the scientific and technical schools as places for the training of medical students. Such institutions specially suit a certain class of young men, but they by no means furnish the best preliminary education for medical students. It has ever to be remembered that the medical art is the art of dealing with human nature more than with chemicals and physic, and the doctor who understands man is much greater than he who understands materia medica. It is on this ground that we have always urged the value of liberal studies over the technical studies in the preparing of young men for medicine.

News of the Week.

The Nomination of Candidates for Coroners takes place soon, and we understand that there are three vacancies. It is greatly to be hoped that Dr. William T. Jenkins will be one of the gentlemen nominated and elected. He has been coroners' physician for eight years, and has done his work faithfully and intelligently, so that he has thoroughly won the confideuce of the profession of the city.

Mississippi Valley Medical Association.—This association will hold its seventeenth annual session at St. Louis, October 14th, 15th, and 16th.

American Rhinological Association.—The ninth annual meeting of this association will be held in Indianapolis, Ind., October 6th, 7th, and 8th.

Missouri Valley Medical Society.—The fourth annual meeting of the Medical Society of the Missouri Valley will be held at Council Bluffs, Ia., September 17th and 18th. The society has a membership of over three hundred.

Extravagant Hospital Administration.—The *Medical Press and Circular* for July 29th refers editorially to the King's College Hospital, London, as an example of "atrocious extravagance" in the conduct of hospital affairs. In the course of a parliamentary investigation the charge was made that this hospital had spent, during the past three years, at the rate of $600 for each bed maintained. The hospital authorities combated this statement by showing that a large sum, about $45,000, had been expended for permanent improvements, but admitted a cost for each bed of $470, of which not more than $84 reached the patient in the bed, the balance, or $386 nearly, being soaked up by secretaries and a multitude of indirect charges. One of the Dublin hospitals, the Cork Street Fever Hospital, long notorious for the monstrous disproportions of its outlay, runs the King's College Hospital a close race for the prize for wastefulness. It reports the gross cost of $595 for each bed, of which $440 represents establishment expenditure.—*N. Y. Medical Journal.*

The New Texas Medical College.—The State Board of Regents of the University of Texas, on the 27th ult., completed the election of the Faculty for the medical department of the State University. Dr. J. M. T. Fleming, of Baltimore, was elected Professor of Surgery, at a salary of $3,000 per annum; Dr. Edward Randall, Galveston, Professor of Materia Medica and Therapeutics, at a salary of $2,500; Dr. Allen J. Smith, Philadelphia, Professor of Pathology, Bacteriology, and Histology, at a salary of $2,000 per annum; Dr. A. G. Clopton, Jefferson, Professor of Physiology and Hygiene, at a salary of $3,000 per annum; Dr. William Keeler, Edinburgh, Scotland, Professor of Anatomy, at a salary of $2,500 per annum; Dr. Seth M. Morris, Austin, Professor of Chemistry, for one year, at a salary of $2,000 per annum, and Dr. George H. Lee, Demonstrator of Anatomy.—*St. Louis Globe-Democrat.*

Medical Students in France.—In the year 1890 there were 7,018 men and women studying medicine in France. Of this number 702 were foreigners.

The Illinois Army and Navy Medical Association was organized at Springfield, Ill., June 26, 1890, with Dr. Hosmer A. Johnson as President, and Dr. John H. Rauch as Secretary. The objects of the society are, the promotion of social, historical, and medical subjects connected with the late war. All reputable physicians now living in Illinois, whether in practice or not, who served in the army or navy during the late war, and all who were surgeons or acting assistant surgeons, who were with Illinois troops, and are now non-residents of the State, are eligible to membership. At the second meeting of the Association, held in Springfield, May 18 and 19, 1891, Dr John H. Rauch was elected President, and Dr. Edward P. Bartlett, of Springfield, was elected Secretary. The Association adjourned to meet in Chicago at the time of the unveiling of the Grant monument. This adjourned meeting will be held at the Grand Pacific Hotel, Chicago, October 7 and 8, 1891.

Dr. James Watt died at his home in Brooklyn, on September 11th, at the age of forty-eight. He was graduated in medicine from the University of Edinburgh and also from the Long Island College Hospital. He served as surgeon during the war, and afterward returned to practise in Brooklyn.

Dr. David Humphreys Storer died in Boston, on September 12th, at the age of eighty-seven. He was born in Portland, Me., March 26, 1804, and was graduated in medicine from Bowdoin in 1822. He was for many years dean and also professor of legal medicine and obstetrics in the Harvard Medical School. He was president of the American Medical Society in 1866, a member of the American Academy of Arts and Sciences, and of the New England Genealogical Society. Dr. Storer was an enthusiastic ichthyologist, and had written a work on the fishes of North America. He was a long-time friend of Agassiz, and was jointly engaged in natural history pursuits with him.

New York State Society of Railway Surgeons.—The first meeting of this Society will be held in the parlors of the Hotel Bensonhurst, at Bensonhurst-by-the-Sea, October 27, 1891. Programmes may be obtained by addressing Dr. George Chaffee, 201 Forty-seventh Street, Brooklyn.

Dr. Peter Pineo died in West Somerville, Mass., on September 11th, aged sixty-six. He was born in Cornwallis, N. S., on March 6, 1825, and was graduated in medicine from Bowdoin in 1847. At the outbreak of the Civil War he went out as surgeon of the Ninth Massachusetts. He was successively commissioned Brigade Surgeon of United States Volunteers, Medical Director of the First Army Corps, and Lieutenant-Colonel and Medical Inspector of the United States Army. The later years of his life were passed in and near Boston.

Dr. Hermann v. Helmholtz celebrated the seventieth anniversary of his birth on August 31st.

A Young Drunkard.—A boy, fifteen years of age, was arrested a few days ago for drunkenness and committed to an institution. He has been several times arrested for the same offence, and was once under treatment at Bellevue Hospital for delirium tremens.

Alphabetical Preference.—A select few of the members of the Congress of Hygiene and Demography were invited, so says *Le Mercredi Médical*, to visit the Queen at the Isle of Wight, and went over to Osborne in a body. After luncheon they were marshalled in line for presentation to Her Majesty, the Germans being first, then the Austrians, and the other nationalities behind them in irregular order. Thereupon the Frenchmen grew indignant, and for a time serious international complications were feared, the trouble being averted only by the presence of mind of a Belgian savant, who suggested to those who had the charge of the arrangements that the members be placed in line according to their nationality, in alphabetical order. This was done, and then the threatening clouds floated off in the direction of the French fleet, Her Majesty smiled graciously on all alike, and Science assumed once more a cosmopolitan character.

Dr. Safford Reynolds, of Granville, N. Y., died suddenly, on September 8th, of heart disease, at Sandy Hill.

A Death under Ether occurred in this city on September 9th. The patient was a man, fifty years of age, who was to be operated upon for removal of a tumor in the side. He was examined previous to the administration of the ether, and presented no symptoms of heart trouble.

The Consumption of Liquor in Germany has assumed such proportions as to alarm the authorities and lead them to the adoption of legislative measures looking to regulation of its sale. The number of cases of alcoholism treated in public institutions in Germany increased from 4,272 in 1877, to 10,360 in 1885. One of the measures proposed for combating this evil is the encouragement of beer drinking by a reduction in the price of this beverage.

The Treatment of a Case of Lupus by tuberculin, which has been carried out continuously by the surgeons of the Marine Hospital Service since February 11th, has at last been abandoned. The medical officer in command at Cincinnati, under date of August 20th, reported that the destruction of tissue by advancing ulceration and sloughing was more marked in the last fortnight of treatment than at any time during the entire period of the existence of the disease, in view of which it was deemed advisable to abandon the use of tuberculin.

Sulfaminol is the name of the latest antiseptic brought out from the German chemical laboratories. It is said to be inodorous and non-irritating.

Woman Physicians are opening for themselves a way in staid old Portugal, four women having passed their final medical examination there this year, two at Lisbon and two at Oporto. Last year one was graduated at Lisbon.

The German Anthropological Congress will meet at Ulm in 1892.

A Bacteriological Institute is to be established in St. Petersburg, under the charge of Dr. Gabrylowicz.

Dr. A. D. Rockwell has resigned the chair of Electrotherapeutics at the New York Post-Graduate School.

Dr. George B. Loring, ex-Commissioner of Agriculture, and ex Minister to Portugal, died at his home in Salem, Mass., on September 14th. Dr. Loring was born in North Andover, Mass., November 8, 1817. He was educated in Franklin Academy of that town and at Harvard College, graduating from the Harvard Medical School in 1842. He was appointed surgeon to the Chelsea Marine Hospital soon after graduation, and served there a number of years. In 1849 he was made United States Commissioner to revise the Federal hospital system. From 1853 to 1857 he was postmaster of Salem. About this time he began to devote himself to practical and scientific agriculture, and was an active member of the New England Agricultural Society for many years, becoming its president in 1864. He gradually retired from medical work and became prominent in public affairs. The cause of his death was dysentery.

Dr. Thomas Magill died on Monday, September 14th, at his home in Freeport, Pa., aged sixty-four. He was born in Westmoreland County in 1827, and was graduated from Jefferson Medical College in 1854.

Annales d'Oculistique.—This well-known ophthalmological journal, edited for many years by the late Professor Warlmont, has, since his death, passed into the editorial hands of Drs. Valude and Sulzer, who have transferred the office of publication from Brussels to Paris. The new management has doubled the size of the journal and promises to increase its usefulness. Dr. George P. Stevens, of New York, is the American collaborator.

A New Hospital in Jerusalem was recently established by the Turkish authorities, but when it came to form the *personnel* of the institution a peculiar difficulty presented itself. The patients would be of all races and religions in proportion to the population of the city, and it was feared that partiality would be shown by the attendants to the patients of their own faith. The majority of the population is Hebrew, the Mohammedans coming next, while the Christians are in a minority. It was thought better, therefore, to select the nurses from the followers of the Christian religion, and consequently the hospital was placed in charge of Sisters of Charity.

Dr. Allen L. Thompson, for nearly fifty years a practising physician at Sandy Creek, N. Y., and the senior member of the Oswego County Medical Society, died during the last week of August, at the age of eighty. He leaves a wife and several children. Among his sons are Dr. Granville S. Thompson, of Washington, D. C., and Dr. Allen R. Thompson, of Troy, N. Y.

Hydrophobia and Syntax.—The good citizens of Connecticut have been considerably alarmed at the prevalence of hydrophobia among the dogs of the State, and many towns have adopted ordinances concerning muzzling or chaining the animals. The selectmen of Unionville seem to have been more than ordinarily frightened, if we may judge from this remarkable notice which they caused to be inserted in the local journal: "By notice elsewhere it will be seen that any persons owning a dog in the town of Farmington are notified that they must be properly muzzled."

The Population of Austria-Hungary increased during the last ten years by 4,781,000. The present population of Austria is 23,896,000, and of Hungary 17,445,000. The increase of population was three per cent. larger in Hungary than in Austria, though Austria is still much the more densely populated. Vienna has a population of 1,365,000.

Taking Proper Precautions.—The *Times and Register* says that New York druggists are very cautious in the sale of poisons. A Philadelphia professor recently found it impossible to obtain a half-ounce of chloroform to remove a grease-spot from his coat until he had written a prescription that would pass the pharmacist's scrutiny. That was eminently proper, and the druggist knew his business. He didn't know to what extremities the poor man might run when he found his vacation in the metropolis nearing its end.

A Rather Useless Ambulance Service is that of London, if we may judge from what is stated in an account of a recent runaway accident. The driver was thrown out of the vehicle and very severely injured, and a messenger was sent out to the nearest police station to call an ambulance. Here he was told that it would not be sent unless it was paid for, and so considerable delay was occasioned, the sufferer meanwhile lying in the street. An ambulance service which will not serve until the cash is in hand, may be of use in giving invalids an airing in the park on pleasant days, but will hardly do for emergencies.

Cancer-grafting. — The cancer-grafting matter has been the subject of active discussion in the European press. One of the assistants of Professor Hahn, writing in a Berlin medical paper, gives the following account of one of the operations: "The case was that of a woman who had visited the hospital a second time, owing to a relapse after having her left breast excised on account of a cancer. The disease manifested itself in such a way that not one of the customary operations was possible. Under the assumption that a partial covering of the cancerous parts with healthy skin would mitigate the pain, Professor Hahn proposed a transplantation, and explained the matter to her, to which, after explanations, she willingly consented. The operation was thereupon performed. Three healthy pieces of skin were transplanted to parts from which the cancerous skin had been removed, and then the pieces of cancerous skin were placed upon the parts whence the healthy flesh had been taken. The healthy skin thrived on the new ground, but the knots of the diseased skin grew larger after two months and a half. On the death of the patient, the knots had reached the size of cherry-stones. Death followed in the natural course, and the transplantation did not hasten it, as the patient felt better after the operation, and did not again complain of pain. On the basis of this experience Professor Hahn expressed the view before the Berlin Surgical Congress, in 1889, that, firstly, cancerous wounds could be healed by the grafting of healthy skin upon them, and, secondly, that cancer is transmissible by the employment of suitable material on a suitable ground." The accused Berlin surgeons were, after a full and careful investigation of the circumstances of the case, acquitted of all unprofessional conduct in the carrying out of their experiments.

Society Reports.

THE INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

Held in London, August 10, 11, 12, 13, 14, 15, *and* 17, 1891.

(From our Special Correspondent.)

(Continued from page 282.)

SECTION ON PREVENTIVE MEDICINE.

THIRD DAY, WEDNESDAY, AUGUST 12TH.

Diphtheria.—A discussion on this subject was opened by DR. SEATON, who said that the cases admitted into the hospitals of the Metropolitan Asylums Board came from all parts of London. He mentioned the case of a village near London—quite free from diphtheria — in which the construction of a new system of sewerage was followed by a severe outbreak; he thought the disturbance of the soil might have led to the freeing of the germs. He said there was a strong ground for urging on Government the necessity for a systematic inquiry into the causes of the disease.

DR. SCHREVENS, of Tournai, said the true origin and the cause of the spread of diphtheria could only be arrived at by examining carefully the results in different countries. In Belgium he had observed that diphtheria and typhoid fever ran concurrently—where one was severe, so was the other, and *vice versa*—but diagrams constructed from the statistical returns showed one exception, viz., Eastern Flanders. One was led to believe that the connexion between these two diseases must be their origin from fecal matter, and the bacteriological researches of Löffler and Eberth agreed with this view. The exception in the case of Eastern Flanders also confirmed this, for the soil here was so humid that it was easily washed clean from all impurities.

DR. HEWITT, of Minnesota, said diphtheria made its appearance in Minnesota about 1860, and was now the commonest cause of death but two, viz., infantile diarrhœa and tuberculosis. Diphtheria started among the families settled on the banks of the great streams, and for some time remained a family disease, but later it spread to the higher plains, when the increasing business of the country led to increased intercourse. It was at first confused with ordinary tonsillitis and with scarlatina anginosa. Dr. Hewitt drew the following conclusions from the information he had been able to collect, viz.: 1. That from twenty to thirty years of age women were more liable than men—a fact which he accounted for by the contagiousness of the disease, and women being generally employed as nurses. 2. That forty-four per cent. of all cases occurred at or under five years of age.

Diphtheria in Massachusetts.— DR. ABBOTT, of Boston, read an elaborate paper on this subject, at the close of which he drew the following conclusions:

1. That diphtheria is an eminently contagious disease. 2. That it is infectious not only by direct exposure of the sick to the well, but also through indirect media, such as clothing and other articles which have come in contact with the sick. 3. That the certainty of infection is not as great as in the case of some of the other infectious diseases, notably small-pox and scarlet fever. 4. That overcrowding, faulty ventilation, and filthy condition of tenements favors its spread. 5. That the influence of defective plumbing is not proven. 6. That its transmission through public and private water-supplies is not proven. 7. That its propagation is favored by soil-moisture, damp cellars, and general dampness of houses. 8. That the poison may remain inactive in houses for a long period.

DR ADAMS, of Maidstone, presented a communication on "The Relationship between the Occurrence of Diphtheria and the Movement of the Subsoil Water."

A Local Examination of the Difference in Susceptibility to Diphtheria Between Old and New Residents.—MR. CHARLES PAGET, of Salford, then read a paper with this title. As the result of his inquiries, Mr. Paget said he found that as the people of a district were more subjected to the continuous influence of their insanitary surroundings, they were found less fitted to resist the infection of this disease. A shorter average period of residence elapsed before an attack of diphtheria was observed where the mortality rate was highest, and *vice versa*. The relative incidence of diphtheria during an epidemic period, in respect of length of residence, was thus dependent to no small extent on general sanitary circumstances.

Professor D'Espine, of Geneva, Dr. Jaussens, of Brussels, and Dr. Escherich, of Graz, continued the discussion, and the opinion was expressed that local disinfecting measures were of great use in preventing the spread of the disease.

DR. THURSFIELD, of Shrewsbury, said that he had long ago arrived at the conclusion that the ordinarily accepted ideas as to the etiology of the disease were one-sided and misleading. He believed that the failure of sanitary improvements to stop the increase of diphtheria was to be attributed to the dissemination of the disease by very mild, medically unattended, and therefore not notified, cases—generally acting through school agency. More importance should be attached to the fact that the chief influence favoring the incidence of the disease was personal susceptibility. He had, some years ago, in published papers, taken the view expressed by Dr. Hewitt, who laid considerable stress on the connection of the disease with damp houses. He had met with cases in which a very prolonged period of infection had been observed, and thought these might be explained by the fact that relapses might occur in diphtheria.

DR TRIPE, of Hackney, said that, as the result of thirty five years' experience, he had noticed that good drainage had but little effect in dimmishing the virulence and extent of epidemics of diphtheria. The best method of preventing its spread was by destroying by fire all rags infected by secretions. He believed the disease was spread by contact, and had found that closing the playground was as effective as closing the school.

Dr. Günther, of Dresden, and Dr. Hubert also spoke, and a resolution was passed by the Section to the effect that it was extremely expedient that European governments should make a comprehensive and systematic inquiry into the causes of diphtheria.

SECTION ON BACTERIOLOGY.

Immunity.—A discussion on this subject was opened by DR. ROUX, of the Pasteur Institute, Paris. He said that the great amount of work which had been done on the subject had one point in common, viz., the attenuation of virus and preventive inoculation, the two subjects with which Pasteur's name would be associated for all time. With the single exception of vaccination, the only method of conferring immunity against any disease was by the inoculation of the virus of the disease. Pasteur had added the less dangerous method of preventive inoculation by means of an attenuated virus, to which he had applied the term vaccination. The term "attenuated" virus ought to be reserved for virus weakened without being attenuated, *e.g.*, by artificially lowering the vitality of the organism for producing it. Two methods of attenuation had been described by Pasteur, viz., 1, the prolonged exposure of a culture to the air at a suitable temperature; and 2, the passage of the organisms through the bodies of different species of animals. Other methods had also been employed. In any case it was necessary that the attenuation should be effected slowly and gradually, rapid attenuation rendered a virus altogether inactive without impressing on it any hereditary weakness. In whatever way the virus was prepared, it must, in order to confer immunity, be brought

into direct contact with the tissues of the animal. Dr. Roux then discussed the theory of phagocytosis, associated with the name of Metschnikoff. Phagocytosis, he remarked, only occurred in refractory animals; in animals susceptible to the disease it was either not to be observed or was incomplete. He then went on to consider the questions whether immunity was the consequence of this power of the cells to include the virulent microbes, or whether immunity might not be due to the absorption of the virus by the cells. Numerous observations showed that the microbes contained within the phagocytes were not degenerated, but were in a condition of full activity. Another demonstration of the importance of the action of the phagocytes was afforded by the fact that even in refractory animals the microbes were found to increase when kept out of the reach of the leucocytes. Thus, if a rabbit were inoculated in the anterior chamber of the eye, where there were no cells, the bacteria grew freely, and their development was only checked when the leucocytes had after a time migrated in large numbers and began to include the microbes. Phagocytosis was thus a very general phenomenon, and one which was very efficacious in checking the advance of the organisms; when it failed the individual succumbed to the virulence of the bacteria. What attracted the cells toward the microbes, and why were the leucocytes, which in refractory animals destroyed the microbes, incapable of seizing upon them in susceptible animals? Metschnikoff propounded his theory in 1883—a theory which rested on two assumptions, viz., 1, that the cells were attracted to the microbes in virtue of a special sensibility which they manifested toward all foreign bodies in the tissues; 2, that this power of seizing upon the virulent microbes in immune animals originated in a habit formed during the earlier struggle with the attenuated virus with which the animal had been formerly inoculated. These preferences of the leucocytes might be more readily explained by assuming that they had a special chemical property analogous to that possessed by the zoösperms of the myxomycetes, viz., that they were attracted by certain bodies and repelled by others. MM. Massaert and Bardet had proved that the products of the microbes exerted a very marked chemical action on the phagocytes. It was at the commencement of the disease that the critical struggle took place; interference on the part of the leucocytes at a later period would be useless, since the microbes would have produced enough poison to paralyze their activity. The theory propounded by Metschnikoff did not exclude the possibility of there being other means of protecting the organism, but it affirmed that phagocytosis had a wider sphere of action and was more efficacious than any other.

Dr. Hans Buchner read a paper on the same subject. He said that down to the present time no general theory of immunity had been formulated. By congenital immunity was meant something specific, dependent on the specific physiological properties, on the one hand of the generating factors of disease, and on the other of the animal body or its individual organs and tissues. With regard to acquired immunity, the experimental conditions of its production were known, but the substance producing the immunity was still unknown. Toxins and toxalbumins must be rejected, also the other metabolic products of bacteria; there remained, therefore, only the specific albuminous substances formed by bacteria, viz., the bacteriproteines. There were three conceptions with regard to the origin of immunity: 1, Want of nutritive material in the tissues and juices, whereby the bacteria were destroyed; 2, phagocytosis; 3, prophylactic substances in the animal tissue-juices. The protective substances were probably albuminous bodies of very unstable composition, and Dr. Buchner proposed the name "alexins" for these bodies.

Mr. Hankin also read a paper. He said the discovery of the bacteria-killing power of blood-serum had led to the view that immunity was caused by a bactericidal action exerted by the blood and lymph of an immune animal. Buchner's hypothesis that this bactericidal power was due to a remnant of "vitality," was unnecessary. He had shown that this power was due to the presence of certain bacteria-killing bodies to which the name "defensive proteids" had been given. That these substances did really play a part in the phenomena of immunity was made probable by the following considerations: 1. While the defensive proteid of the rat could be used to protect mice against virulent anthrax, the defensive proteid of an animal susceptible to this disease possessed a far feebler bacteria-killing power, and could not be so used. 2. By feeding wild rats on bread and water they could be rendered susceptible to anthrax, and at the same time their defensive proteid dimmished in amount. 3. Very young rats, which were known to be susceptible to anthrax, contained only traces of the defensive proteid. He proposed the following physiological classification of defensive proteids: 1, Sozins (defensive proteids present in the normal animal); 2, phylaxins (defensive proteids present in artificially immune animals). Each of these groups was divisible into two subgroups, viz., myco-sozins, toxo-sozins, and myco-phylaxins, toxo phylaxins—the myco group comprising proteids which acted by killing the microbes, and the toxo group those which acted by destroying microbic products. Mr. Hankin suggested that possibly defensive proteids were the weapons used by the phagocytes in their conflict with the microbes.

Professor Emmerich, of Munich, said bactericides were probably intermediate products of decomposition, a stage in the passing of albumin into fat. Hence it was probable that the blood and tissues of immune animals, which contained matter energetically poisonous to bacteria, must also act as a remedial agent in infective maladies, if injected subcutaneously. This conclusion had been recognized experimentally in two infectious maladies, viz., swine erysipelas and croupous pneumonia.

Mr. Adami, of Cambridge, said the bacteriological world was at present divided into two opposed camps, viz., those who held that microbes within the system were destroyed by the agency of the living cells, and those who held that the function of microbic destruction was performed by the blood-serum and body fluids in general. Any observer could not fail to be struck with the prevalence of phagocytosis, and it was quite possible to accept both views.

Dr. Klein remarked that ordinary frogs and rats were insusceptible to anthrax, but these animals had been made susceptible thereto by a variety of means, which seemed to indicate that there were certain chemical conditions at work.

Dr. Metschnikoff then spoke. Messrs. Behring and Kitasato, he said, had discovered the bactericidal power of the serum of guinea-pigs inoculated against the vibrio Metschnikovii, and had shown that whereas this vibrio developed readily in the serum of guinea-pigs which were susceptible to the malady after its being in the body from three to five hours, it was destroyed in the body of the inoculated guinea-pig; the serum of the inoculated guinea-pig killed the vibrio in a very short time, whereas in the serum of a susceptible guinea pig the vibrios developed in great numbers. Animals completely inoculated against infection were as susceptible to toxic doses of sterilized cultures as animals not inoculated at all. The inoculated guinea-pigs died after the same dose as those not inoculated, and the inflammatory and febrile phenomena were the same. In the septicæmia of guinea-pigs the phagocytes had the most important action of all the immunity factors. The bactericidal power of the serum, remarkable as it was, did not confer immunity. Behring himself had admitted the insufficiency of the theory founded on the microbicidal power of the body fluids As proved by Messrs Vaillart and Vincent, the animals which were subject to tetanus were already naturally refractory to the microbe. In this immunity from the microbe it was the phagocytes which played the principal part.

Dr. Wood described the protective influence as probably "a specific memory of the cells" which must be acquired gradually, and Professor Babes thought the protective substance was probably of the nature of albumose as shown by precipitation experiments.

SECTION ON THE RELATION OF THE DISEASES OF ANIMALS TO THOSE OF MAN.

Infectious Udder Disease of the Cow in Relation to Epidemic Diseases in the Human Subject.—Dr. Klein introduced a discussion on this subject. He said that in several epidemics of scarlet fever brought about by milk, Mr. Power had established that the infectiveness of milk was not due to contagion from a human source, but that probably a pathological condition of milch cows, undiscovered before 1885, played a prominent part in giving to their milk the power to produce scarlet fever in the human subject. Dr. Klein then referred to three epidemics of scarlet fever referrible to cow disease. Another epidemic disease referrible to cow disease was the so-called "Edinburgh" disease. Diphtheria was also traceable to cows. Dr. Klein expounded his views on this subject at some length, and was followed by Mr. Armstrong, Medical Officer of Health for Newcastle, Dr. Turner, M. O. H. for East Staffordshire, and Dr. Bostock, M. O. H. for Birmingham, who narrated examples of outbreaks of disease caused by milk.

Professor Crookshank then spoke, and took the opposite view, one which he has previously put forward strongly in opposition to the theory supported by Dr. Klein, viz., that there was no evidence in support of the theory that these specific diseases in the human subject ever arose from eruptions or skin diseases of the cow. Professor Crookshank gave an account of some investigations on the subject which he had conducted for the Veterinary Department of the Board of Agriculture.

Dr. Ostertag, of Stuttgart, thought scarlet fever was not communicable from man to animals. Loeffler had failed to produce the disease in the cow by inoculation.

Mr. W. Hunting, F.R.C.V.S., and Dr. W. J. Collins spoke against Dr. Klein's views.

Professor Chauveau, of Paris, said that some years ago he had endeavored to transmit the small-pox virus to animals, but had failed. Since then, however, he had been more successful, and had found himself able in every case to communicate the small-pox virus to bovine animals, but he had never succeeded in transforming this small-pox virus into vaccine.

Infection of Meat, Milk, and Other Comestibles.—Dr. Ballard read a paper with this title, and after discussing the subject very fully drew the following practical conclusions: That if we eat bacon or ham, cold or warm, it is a proper precaution to avoid them if not duly cooked throughout. The grand precaution of all was the very commonplace one signified by the word cleanliness. Every factory where pork was converted into brawn, or hams, ought to be so arranged that light and a draught of air could penetrate everywhere; there should be no corners where dirt could lodge and micro-organisms be cultivated; the rise of ground air should be obviated by cement under the floor, and the place should be kept scrupulously clean. Pantries, etc., should be similarly cared for.

The Infection of Meat and Milk.—Dr. Victor C. Vaughan, of the United States Army, read a paper on this subject. He said such infection might be caused in any one of three ways, viz.: 1, From a diseased condition of the animal from which these foods were obtained; 2, from the inoculation of these foods with specific pathogenic micro-organisms outside the body of the animal from which they were derived; 3, meat and milk might be infected with saprophytic toxicogenic bacteria. The author discussed the subject under these heads, and also remarked that it was not necessary for food to be infected with some specific micro-organism before it could be rendered unfit for food. As an example, a case was mentioned in which milk caused vomiting and purging; it had stood for two hours in a very filthy atmosphere.

Professor Blanchard, of Paris, Professor Brown, and Mr. Fleming, F.R.C.V.S., joined in the discussion.

SECTION ON INFANCY, CHILDHOOD, AND SCHOOL LIFE.

Mr. Diggle gave his presidential address, the chair being meanwhile occupied by Dr. Jacobi, of New York.

Overwork in Schools.—Dr. Leo Burgerstein read a paper in which he laid down the following propositions: 1, That it was desirable that the question of mental overpressure should be investigated by exact experimental methods; 2, that in the meantime school lessons should generally not last longer than three-quarters of an hour. These were subsequently carried as resolutions.

Exercise in School.—Mr. George White, Chairman of the Committee on Physical Education of the School Board for London, read a paper on "Physical Education," which was illustrated by a number of exercises performed by children from a Board School.

Dr. Brosnan read a paper on the same subject, and a discussion followed, after which resolutions to the following effect were carried: That the hours of home work for children in schools should be restricted; that ample physical recreation be carried out; that in the interval between the exercises the body should be properly rested.

The Value of Hygiene to Women.—Dr. Schofield read a paper on this subject, and at the close of it proposed the following resolution, which was carried unanimously, viz.: "That this Congress hereby warmly advocates the instruction of girls and women in personal and domestic hygiene as an integral part of their education."

SECTION ON CHEMISTRY AND PHYSICS IN RELATION TO HYGIENE.

The Chemical Treatment of Sewage was the title of a paper by Dr. Thresh, in which he gave an account of the various chemical methods employed. With reference to the electrical treatment of sewage, he said that an extended series of experiments on a much larger scale would be necessary to convince the sceptical that this was other than a roundabout way of producing a soluble iron salt to act as a precipitating agent.

Dr. Alfred Carpenter spoke in favor of sewage farms, and several speakers supported his views. At the close of the discussion the following resolution was proposed by the President, Sir Henry Roscoe, and carried, with some dissentients: "That in the opinion of this meeting the best yet known method of disposing of the sewage of towns is that of purification and utilization on the land."

SECTION ON NAVAL AND MILITARY HYGIENE.

Dietary Scales in Connection with the Health of Seamen.—Dr. W. Spooner, in opening the discussion of this subject, said the ordinary dietary scales were not fitted to preserve health. They were too monotonous, had too much salt meat, not enough vegetables, and the proportion of different ingredients was not correct. Preserved meat should replace salt meat, and vegetables should be added. On American ships potatoes were always given. Owing to too much meat the nitrogenous ingredients in the present scale were in excess; the saving effected by reducing the quantity of meat might be expended on other articles. If a proper dietary scale were made compulsory, scurvy would in a short time be eradicated.

Scurvy.—Dr. Rae, F.R.S., narrated his Arctic ex-

periences of scurvy. He was surgeon to the Hudson Bay Company's ship Prince of Wales in 1833–34, when he was twenty years of age. During two winters in the Arctic regions his party lived practically without vegetables, but their provisions were fresh, and all killed by themselves. The Eskimos used very largely the contents of the deer's stomach in the winter as a vegetable, cutting off a piece and eating it as if it were bread. He strongly recommended cranberries as part of the ration, both in the navy and in the mercantile marine. They were easily preserved with a little sugar. When cranberries were found in the Arctic regions improvement began in all his scurvy patients.

Dr. Collingridge said there could be no question as to the inefficiency of the diet scale, and even this was not obtained at its paper value.

Mr. Swanston said the dietary scale was not at present compulsory, and power would have to be given by Parliament before the Board of Trade could force a scale upon the Mercantile Marine.

SECTION ON STATE HYGIENE.

State Control in Reference to the Homes of the Working Classes.—Papers were read on this subject by Dr. Elgin Gould, of Washington, Mr. John Hamer, Dr. Theodore Thomson, Mr. G. M. Burroughs, and one by Mr. Henry Rutherford. An animated discussion followed, in which most of the speakers expressed themselves in favor of State control, though some objections were raised.

Dr. Elgin Gould, in replying, said that most of the difficulties mentioned had been solved in the United States, and suggested a study of the sanitary legislation of the city and State of New York.

Dr. Danford Thomas then read a paper on "State Control of the Sale of Poisons." At the close of the discussion on this paper the following resolution was proposed and carried: "That in the opinion of the International Congress of Hygiene and Demography it is essential, in the public interests, that the existing law regulating the sale of poisons should be amended, and greater restriction placed on the sale of poisons, and this especially in Great Britain and her Colonies."

Division of Demography.—The first paper read in the third day's session was on "The Temporary Migration of Labor," by Mr. Ravenstein. This was followed by one by M. Levasseur on "Migration within France." A discussion on "The Suitability of Tropical Highlands for European Settlement" was introduced by Dr. Felkin, and papers read on the subject by Surgeon-General Sir William Moore, Dr. Van der Burg, and Mr. Clements Markham.

Dr. Van der Burg concluded that the colonization of tropical highlands was physiologically possible, but that field labors would have to be excluded, and that such colonization was not possible for economic reasons.

Mr. Fox read a letter from Dr. Giles, written in India, in which Dr. Giles ridiculed the notion that there was any marked difference between English children brought up in India and those brought up in England.

Professor Stokvis, of Amsterdam, denied that there was such a disease as tropical anæmia.

Surgeon-General Ewart thought there was no chance of elevated tropical regions ever becoming colonized by true Europeans.

Mr. Haviland read a paper on "The Influence of Clays and Limestones on Medical Geography," and Mr. William Tapley one on "The Influence of Geology on Health and the Districts of Disease." At the close of the latter, Sir Henry Acland made a few remarks on the difficulty of the subject. He suggested that the greater prevalence of phthisis on damp soils might be due to the bacillus tuberculosis requiring such soils for their life and growth, so that geographical conditions would only in a secondary manner influence the prevalence of phthisis.

Fourth Day, Thursday, August 13th.

SECTION ON PREVENTIVE MEDICINE.

The Use and Abuse of Alcohol.—Sir Dyce Duckworth said he felt he approached the subject in a proper spirit in one way, for he was temperate in his views on it. He maintained that alcohol was not an unmixed evil, and remarked that there were other forms of excess, so that we might as well talk of abolishing bread-and-butter as alcohol. He believed the abuse of alcohol was less prevalent than formerly. There was no evidence to show that the moderate use of alcohol was injurious, but the question at once arose, what was moderation? In his opinion from one ounce to one ounce and a-half of alcohol per day—in whatever form taken—was sufficient for an adult (children required none). This amount should be taken with a meal, and preferably when work was done. If the use of alcohol to this extent were not harmful, it was actually beneficial. Turning to the question of misuse, he expressed himself in favor of a certain amount of local option. He classed the examples of chronic drunkenness under two heads: 1. The foolish, callous, vicious drunkard. 2. The victim of inherited, or, in some cases, acquired nervous disease. Physicians alone could discriminate between the two classes, but, having done so, the treatment of the second class should be medical. But the first class should be stringently treated.

Professor Westergaard, of Copenhagen, then read a paper on "The Relation of Alcoholism to Public Health and the Methods to be Adopted for its Prevention." He disapproved of Maine laws and of local option, but thought the high license system was more effective. He considered a limitation of the hours was quite necessary, and pointed out that in Norway the sale of spirits was forbidden from Saturday afternoon till Monday morning.

M. Milliet, of Berne, said that from the scientific stand point the State had no right to interfere, and from the practical stand point it had no power to do so.

Dr. Norman Kerr spoke in favor of total abstinence.

Sir Joseph Fayrer said he was no advocate of total abstinence, but he held that principles of temperance should be most strongly inculcated and form part of every child's education and training.

Several speakers joined in the discussion, which was brought to a close by Sir V. K. Barrington, who spoke of the connection between drunkenness, lunacy, and idiocy, and strongly upheld the Norwegian system, which had transformed that country from the most drunken to the most sober in Europe.

SECTION ON BACTERIOLOGY.

Tuberculosis.—A discussion on tuberculosis was introduced by Dr. Burdon Sanderson, who dealt chiefly with the question of etiology. He said there were not as yet enough facts to say definitely that tubercle taken by the intestine produced general tuberculosis, but in children tubercles of the intestine were followed by tubercles of the glands and the bones, so that we might infer that the same might occur in the adult. We were in great want of more experimental research. More evidence was wanting as to the cause of tubercle in infancy. With regard to government administration, Dr. Sanderson advised a strict system of inspection extending over the whole country, acting equally in different parts. Tubercle should be included in the Infectious Diseases Prevention Act. About five per thousand of cattle were generally condemned as tuberculous. This involved compensation which would involve (very small) extra taxation.

The Alleged Danger of Consuming the Apparently Healthy Meat and Milk of Tuberculous Animals.—Professor Bang, of Copenhagen, read a paper with this title. He described some experiments which he had made, and said that, on the whole, he did not think the milk from a tuberculous cow, with udders apparently healthy, was dangerous, though it was sometimes so, and

was always suspicious. Meat was not a source of danger so long as the malady was localized.

On the Transmission of Tuberculosis from Animals to Man, by means of Flesh and Milk, derived from Tuberculous Animals.—This paper was by PROFESSOR MCFADYEAN and DR. SIMS WOODHEAD. They thought the main cause of tuberculosis was from animals. The danger of tuberculous milk, however, was diminished by dilution with sound milk. There was great necessity for a fortnightly inspection of milch cows by a veterinary surgeon. No phthisical person should be allowed in a dairy.

M. ARLOING proposed that the etiology of tubercular disease of early infancy, between three months and five years, be referred for discussion to the next Congress. This was seconded by Dr. S. Gibbon and carried unanimously.

The President, SIR JOSEPH LISTER, said he was pleased to find that spontaneous tubercle was never seen in the sheep, so we could eat mutton with safety.

Koch's Method.—PROFESSOR EHRLICH read a paper on "Koch's New Method of Treating Tuberculosis," and described the methods of Moritz, Biedert, Guttmann, and Langenbrich. All of these processes were based upon the application of small but repeated doses, of gradually increasing strength, and their advantages were that the undesirable inflammatory effects of the remedy were avoided.

PROFESSOR CORNIL, of Paris, DR. BARDACH, of Odessa, DR. PENFICK, and PROFESSOR HUEPPE narrated their experiences with tuberculin, and DR. HUNTER described some experiments he had made, in which he had succeeded in isolating three substances, viz., one which caused fever but no local action; 2, one which caused local action but no fever; 3, one which gave neither, but had the remedial effect.

The Inspection of Meat with Regard to the Prevention of Disease.—DR. FRANCIS VACHER read a paper on this subject in which he urged the adoption of the following measures: The general provision of public abattoirs; closing of private slaughter-houses; licensing and registering of all butchers and their premises; appointment of competent inspectors of meat; general systematic inspection of animals and meat intended for food; appointment of competent assessors to sit with magistrates, and assist them when necessary in the hearing of cases relating to diseased meat.

SECTION ON INFANCY, CHILDHOOD, AND SCHOOL LIFE.

Children and the State.—The first paper read was on "Neglected Children in our Towns and Cities," by MR. WILLIAM MITCHELL, Chairman of the Glasgow School Board, who proposed legislative, social, and individual remedies. A discussion followed, and then Dr. Victor Desguin read his paper on "The Treatment of Orphans Considered in its Physical and Moral Aspects."

The REV. J. LLEWELLYN DAVIES read a paper on "Free Dinners for School Children." An animated discussion ensued.

MRS. BESANT proposed a resolution which was finally carried in the following amended form: "That this Congress, asserting the duty of the state toward its future citizens in the matter of education, declares that the feeding or clothing of destitute or neglected children is necessary for their efficient education. Where such destitution or neglect is due to the misconduct of the parents or guardians of the child, it is the duty of the legislature to visit that miscouduct with penal consequences."

SECTION ON CHEMISTRY AND PHYSICS IN RELATION TO HYGIENE.

Contaminated Water-Supply.—DR. PERCY FRANKLAND read a paper on "The Present State of our Knowledge Concerning the Self-purification of Rivers." He contended that the evidence of self-purification was wholly inadequate to justify the use for town-supply of river water which had received sewage contamination.

A number of papers on the disposal of house refuse were read and discussed, an almost unanimous opinion being expressed in favor of the destruction by fire of such refuse.

SECTION ON STATE HYGIENE.

Disposal of the Dead.—A discussion was inaugurated by the reading of a paper by SIR HENRY THOMPSON, entitled "Recent Proposals Relating to Burial and Cremation, and the Importance of Disinfecting all Bodies Dying from Infectious Disease, with Remarks on the Present System of Certifying the Cause of Death." The author maintained that the ordinary method of burial was a danger to the living—especially in the case of persons dying from zymotic disease—and that pollution of sources of water-supply was a common occurrence in the neighborhood of graveyards and cemeteries. He admitted that in light, dry soils and elevated spots—the most salubrious, he remarked, for human habitation—it might be possible to adopt interment in perishable coffins or in close contact with the soil itself. Cremation, however, was preferable. For bodies certified to have died from infectious disease it should be made compulsory to either cremate them or bury them in capacious coffins filled with quicklime. In view of the increasing preference for cremation it was essential to demand, at the same time, that the official determination of the causes of death should in all cases be more complete than had hitherto been the case in this country.

Rational Disposal of the Dead.—MR. SEYMOUR HADEN followed with a paper on "The Rational Disposal of the Dead: A Plea for Legislation." In this paper Mr. Haden reiterated the views he has so long advocated as to the desirability of earth-to earth burial. He has for many years been active in directing attention to the evils of the present system of interment, and his paper was a very interesting *résumé* of the subject. He contended that in earth-to-earth burial the decomposition of the body was accomplished rapidly in an innocuous manner, and that cremation was not only unnecessary but an incentive to crime.

A discussion ensued, which was on the whole favorable to cremation, and the following resolutions were passed with only a few dissentients: "That governments should be urged to remove all legislative obstacles to the cremation of bodies." "That governments be urged to adopt cremation of bodies on the battle-field." "That the cremation of the dead is a rational and hygienic procedure, which is especially called for where death occurs from contagious disease."

SECTION ON NAVAL AND MILITARY HYGIENE.

Enteric Fever.—A discussion on this subject took place, introduced by papers by Dr. Lane Notter, Surgeon A. M. Davies, Dr. J. Edward Squire, and Dr. Schneider.

DR. NOTTER concluded that the apparent increase in the mortality from enteric fever in India was due to the fact that deaths formerly returned as from remittent fever were now returned as from enteric fever.

DR. DAVIES thought the enteric fever of campaigns was of pathogenic origin, due to a specific bacterial parasite, which parasite need not necessarily be derived from a pre-existing case, but might have developed its specific characters and disease-producing properties by a process of evolution under favoring conditions.

DR. SCHNEIDER said that the diminution in typhoid sickness and mortality in the French Army had not only been continuous but also progressive.

BRIGADE-SURGEON STAPLES drew special attention to two chief factors underlying the development of the disease in India, viz., the undue susceptibility of the newly arrived in the country, and the still greater susceptibility of those who arrived at an undue season of the year. He

drew the practical conclusion that as regarded the Bengal European Army it was necessary to retain the soldiers and to resort to the old system of landing troops in that country which gave them the cold weather before the dry season began.

Surgeon-General Marston concurred as to the importance of selecting the right season for sending out our troops to hot climates, and, in case of war, he thought more might sometimes be done in the selection of regiments.

Brigade-Surgeon Harvey said he had seen many cases of enteric, and many of remittent, fever; many also of a fever which used to be returned as remittent but which was now entered as enteric, thus raising the apparent numbers of the disease. In these cases the temperature charts did not correspond with the typical charts given by Wunderlich and others. He had for some time thought there might be another variety of fever intermediate between enteric and remittent, yet differing from the one in important particulars—especially the range of temperature and the pathological appearances, and from the other in not being influenced by quinine. In our last little war on the Miranzai frontier fourteen cases of remittent fever were returned among the native troops and followers, and among the British troops, while six cases among the latter were returned as enteric. If we accepted Surgeon Davies's theory of possible origin there was no difficulty in accounting for them; but if we considered the disease to have a specific origin, then, as the men had left India longer than the longest supposed incubation period, and the native population knew nothing of a fever lasting three weeks and ending in death, it was difficult to account for them. None of the men died, but the temperature charts did not correspond with the Eastern type, and were similar to those of the remittent-fever cases among the native troops. He thought that pending further investigation the term typho-malarial, as recognized by the American nosology, might be used provisionally and as a matter of convenience. He did not consider that the use of this term implied a belief that enteric and malarial fever were combined, the typhoid state being common to many diseases.

Brigade-Surgeon Maunsell said that in India troops in cantonments could be protected by improving the conservancy; the system might be good theoretically, but practically it was very faulty.

Surgeon-Major Robinson said typho-malarial fever was a disease worthy of more investigation. The name had lately been admitted to our nosology, but it did not seem to him a good one, as a combination of two specific fevers did not constitute a separate disease. The disease differed from ordinary enteric in important respects—especially as to prolonged incubation and protracted convalescence. It occurred very largely in recent Egyptian campaigns.

Dr. Godfrey, of the U. S. Marine Hospital Service, said that a series of cases observed in the hospital of which he had charge, in which the typhoid fever was interfered with so as to cause a suspicion of mixed disease, showed by culture methods and microscopic examination that the patients were all invaded by the bacillus of Eberth, and the plasmodum of Laveran. These patients all came from one place, had drank the same water, and been subjected to the same miasm. In America those places were most exempt from typhoid where river water held in upper ground cisterns was drunk.

Brigade Surgeon Key said typho-malarial might or might not be a good name, but for the safety of the soldier we should do well to look at doubtful cases as belonging to the graver or enteric form.

Dr. Cayle said one of the modes of spread of typhoid fever, cholera, and other diseases which probably depended on the introduction of a definite poison into the system, was by means of the dust carried in the atmosphere. This applied to India and nearly all continental countries.

Professor Notter and Dr. Davies then replied. The former said, in reply to Surgeon-General Marston, that we must prevent specific disease by studying the environment of specific cause. Take cholera bacilli. They would not grow in an acid medium. The stomach was alkaline after fasting. The practical bearing of this was to use acid drinks and not to enter a hospital when the stomach was empty. Future research would tell us what were the conditions most favorable to Eberth's bacilli. As a practical conclusion he would say, "Dry your soil, and endeavor to control the variation in the water-level." He did not think Brigade-Surgeon Harvey's cases were enteric.

Dr. Davies, in reply, said nearly all the speakers endorsed the pathogenic theory of origin. This was a justification for his dwelling on the fact that the experience of army medical officers was not in accordance with current teaching as to the necessity of a specific contagion. The most recent bacteriological investigation tended to show that there was not one micro-organism responsible for the causation of typhoid fever, but several. This harmonized with the experience of army officers that there was more than one form of fever met with in campaigns. Evolution might cause these variations.

Division of Demography.—Mr. H. S. Hallett read a paper on "India Factory Legislation." Mr. Hallett urged that there was a case for protecting workshops and minor factories which had been excluded from the Act. Owing to this exclusion, children of any age might be employed in workshops for any number of hours by day or night, and under most insanitary conditions.

Madame le Dr. A. C. Katchef read a paper on "Home Work in Russia," in which she said the economic and hygienic position of such workers (known in Russia as "konstari") was deplorable.

Relative Ages of Husband and Wife.—Dr. Joseph Körosi, Director of Municipal Statistics, Buda-Pesth, then read a paper on "The Influence of the Age of Parents on the Vitality of their Children." The author urged that girls should not marry at all under twenty, and that women under thirty, or even thirty-five, should avoid marriage with men over fifty. Women above thirty-five had no unfavorable chances to fear by choosing a husband above fifty, and these same women, and even those from thirty to thirty-five, would do well to avoid union with young men, as it seemed probable that their children would be more exposed to hydrocephalus or inborn debility. Males should therefore generally renounce to the youngest girls under twenty or nineteen years of age; if between twenty and thirty, they should avoid marrying women above thirty-five; if at the age of fifty, they had approached the end of male generative power, and they should select no younger woman than above thirty-five.

Dr. Singer remarked that the variation of mortality of children in relation to the age of mothers, as shown by Dr. Körosi, might be in connection with the fact that the marriage age among the working classes was a comparatively young one, whereas among those in a better social position marriage took place later.

The President, Mr. F. Galton, F.R.S., thought much useful information on the subject might be obtained from a careful study of well kept stud-books.

Dr. Longstaff observed that the births in each year were due to marriage in many preceding years. We did not know how many resulted from marriages that had taken place in the immediately preceding years.

Fifth Day, Friday, August 14th.

SECTION ON BACTERIOLOGY.

Disinfection of the Living Body.—Dr. Hunter gave a *résumé* of Dr. Behring's paper on this subject. The author said that down to 1883 it was not thought possible to render harmless pathogenic germs in the living

body, but the work of Pasteur and Koch had shown this theory to be false. Antiseptics acted both on the bacilli and on their chemical products, so that disinfection must be held to apply to these poisonous chemical products as well as to the bacilli themselves. The spleen of a mouse dead with anthrax was rendered innocuous by exposure to the blood of an animal "immune" to anthrax. The action of a combination of corrosive sublimate and chloroborate of sodium was very marked. The disinfecting power was only seen in animals after subcutaneous injection close to the original inoculation one or two minutes after such inoculation had been made. But the action was partly general, producing general changes in the blood which rendered it unsuitable to the growth of anthrax bacilli. Behring concluded that there was a great future before us in the discovery of these valuable combinations. In diphtheria the best chemical disinfectant was terchloride of iron. Corrosive sublimate and zinc, as described by Lister, were also effective. After animals had acquired a certain degree of immunity, these chemical agents acted in a different way. The results of his experiments showed that not only the bacilli but their chemical products were acted on. It was doubtful whether we could influence the functions of living cells for curative purposes. In the general treatment of infectious disease we must recognize the principle which Lister had applied in the local treatment of traumatic lesions, viz., to keep away or make innocuous the heterogeneous causes of disease, but to leave in quiet living cells and living tissues.

Dr. Roux inclined more to the belief that immunity was conferred by the direct action of the cells on the bacilli than by any chemical action which he regarded as incomprehensible.

The President said he regarded phagocytes as one regards higher animals which are gifted with an intelligence, and not only a chemical action. He thought we must not look merely to chemical action.

Testing Disinfectants.—The next paper was by Professor Max Gruber on "The Methods of Testing Disinfectants." The author showed that when tested by proper methods, such as he described, the disinfectant powers of most substances proved to be considerably less than had usually been conceived. In his experience the best agents proved to be carbolic acid, lysol, and a preparation of kresole which he had recently had prepared.

Immunity.—Next followed a paper by Dr. Armand Ruffer on "Some Experiments on the Mechanism of Natural and Artificial Immunity." The author's experiments were chiefly made with the bacillus chauvœi (charbon symptomatique, Rausch-brand, quarter evil), and as the result of them he arrived at the following conclusions: That the natural immunity of rabbits, and the artificial immunity of guinea-pigs was not due to the absence of nourishing material. That the dead serum of non immune animals had a more powerful action on the bacillus chauvœi than the serum of immune animals; the living fluids of non-immune, naturally immune, and artificially immune animals had no power of destroying the same. By allowing an extremely weak virus to grow in the living fluids of a naturally or artificially immune animal, and protecting it from the action of the wandering cells the virus became so intensified that when re inoculated into the same or any other immune animal it caused death. The living fluids of a febrile animal had no bactericidal powers for the micro organisms which produced the fever. The virus which, protected from the action of wandering cells, had lived for three, five, seven, or more days in the living fluids of febrile animals became extremely intensified. The inflammatory reaction, or rather the emigration of wandering cells to the point of inoculation, was inversely proportional to the number of micro organisms introduced. The number of micro-organisms which penetrated from the point of inoculation into the tissues and general circulation was inversely proportional to the number of wandering cells which had emigrated to the points of inoculation. There was evidence that the leucocytes were attracted to the point of inoculation by a chemical poison, and that they absorbed bacilli while the latter were still alive. He had found experimentally that in acute infectious diseases the leucocytes did not emigrate, and that the absence of inflammatory reaction was not solely due to paralysis of leucocytes, or to vascular alterations, but to other and more complex causes. Experiments showed also that though leucocytes refused to emigrate, they might be very active, and whenever they were prevented—either mechanically or otherwise—from reaching the virus, the disease ended fatally in naturally or artificially immune animals. Iodine in certain strengths had an attraction for leucocytes, while lactic acid and benzol repelled them.

Dr. Roux read a paper on "The Practical Value of Preventive Inoculation" in which he maintained the superior value of preventive inoculations with attenuated virus over chemical inoculations.

Professor Babes read a paper on "Rabies and its Treatment." He said Pasteur's method was, with certain modifications, the best treatment. Professor Babes had, as long ago as 1886, pointed out the necessity for the passage from weak to strong injections being regular. The patient should be inoculated as soon as possible after infection. Bites in the neighborhood of, and involving nerves were most fatal, hence the depth of the wound and its situation were of importance.

SECTION ON THE RELATION OF THE DISEASES OF ANIMALS TO THOSE OF MAN.

Actinomycosis.—A discussion on diseases communicable from animals to man, and *vice versa*, was opened by Professor Crookshank, who said he would deal exclusively with a disease common to man and animals which had interested him for some years more than any other, viz., actinomycosis. This, he said, had frequently been referred to as a new disease, but the various manifestations of it had been met with for more than half a century, though misunderstood and misnamed. From contemporary literature there could be no doubt that it was very prevalent in Scotland in 1827–39. Professor Crookshank described its various manifestations, and referred to its prevalence in Australia and the United States. In man, as in cattle, cases of actinomycosis had been met with and not recognized as such. By the researches of Israel and Ponjick in Germany, and the recognition of a case in man by Acland in this country, a new field of inquiry had been opened up. The disease was not new in man, but it had not been differentiated from the diseases which it simulated. In 1848 M. Louis met with a pulmonary affection supposed to be cancerous. Mr. Lebert found in the pus—and made a drawing of—the tufts of club-shaped elements with which we were now so familiar. Nearly two hundred cases in man had been described, and about five per cent. had occurred in this country. Professor Crookshank suggested that the resemblance of the disease to tuberculosis might explain the reports of a very high percentage of cases of tuberculosis in cattle, both in this country and the colonies. He thought the disease was rarely, if ever, the result of direct infection from cow to cow, or from cow to man. There was reason for believing that man and animals derived the disease from a common source, and a strong suspicion attached to cereals.

Professor Ponfick said he agreed with Professor Crookshank. In cattle the disease was generally transmitted by food.

Professor Nocard referred to the irregular geographical distribution of the disease. He thought the disease spread in certain food-stuffs, and that in certain districts the pasture was infected with the germs of the parasite. In a recent outbreak a large number of wolves and cows were all attacked simultaneously with the different forms of the disease. In such a district man could

also be infected if he ate green food uncooked. The question of man infecting animals, or animals affecting man did not seem to Professor Nocard to arise.

Dr. Salmon said the statements in regard to the prevalence and contagiousness of actinomycosis in the United States has been greatly exaggerated. So far from there being four or five per cent. of the bovine animals in the United States affected with actinomycosis, it was probable, from the results of the national inspection recently established, that there were not over one or two per thousand among the beef cattle which arrived at the stock-yards. Public opinion in the States would not tolerate the utilization of the carcases of animals affected even in the slightest degree.

Mr. Goodall, of Christchurch, said our present knowledge seemed to prove that the parasite was a fungus which found its normal habitat in vegetable structures and was only accidental in animals. He suggested that a conference such as the present should carry their deliberations to the utmost, and not rest with the diseases communicable from animals to man, but from the vegetable to the animal world. He begged to call attention to the part played by the larvæ of dipterous insects from a hygienic point of view. These larvæ were reported to feed on decomposing organic matter, but their mouths were so constructed that this was impossible; doubtless they fed on the lower forms of animal life and thus kept these forms of life in check.

Professor Walley said he was not previously aware that internal lesions were commonly found in cattle. Professor Crookshank's remarks showed the necessity of dealing with actinomycosis as a contagious disease equally with tuberculosis. He failed to see how it could be held not to be contagious. The sooner the better the disease should be scheduled, together with tuberculosis, as a contagious disease.

Mr. Barrett said the disease was most frequently found on heavy land; on light land it was almost unknown.

Professor McFadyean did not think actinomycosis was very frequently confounded with other diseases by veterinary surgeons. He was interested to hear that it had been confounded with tuberculosis in Australia; this confusion was probably responsible for the statements as to the prevalence of tuberculosis among cattle that had never been housed.

Sir Henry Simpson, of Windsor, said he was content to recommend the consumption of the flesh of infected animals, always excluding the locally diseased parts.

Professor Crookshank then replied. He said that as to the question of the disease being confounded with tuberculosis, there was no doubt the great fear which had arisen in consequence of the statement as to the prevalence of tuberculosis would be allayed if it were found that the less serious disease, actinomycosis, had been confounded with it. His remarks applied more particularly to those cases of what had always been considered scrofulous, but which were really examples of actinomycosis.

SECTION ON INFANCY, CHILDHOOD, AND SCHOOL LIFE.

The Care and Treatment of Epileptic, Mentally Feeble, and Imbecile Children, was the title of a paper read by Dr. Fletcher Beach. The author said that these constituted three perfectly distinct classes of cases, and the care and treatment of each should proceed on different lines. He proposed that homes should be prepared for epileptic children where they could be trained mentally and physically, and where medical treatment could be pursued. He suggested that auxiliary schools, similar to those in Norway and Germany, should be established for feeble-minded children, in which instruction adapted to their powers should be given by teachers experienced in the methods required to call out the faculties in such cases. He remarked that the provisions at present made for imbecile children were very defective.

The next paper read was by Dr. Shuttleworth, on "The Care of the Mentally Feeble Child, as Distinguished from the Imbecile." A paper by Dr. Kotelmann followed. Some discussion ensued, and the following resolution was carried: "That this Congress do appoint a commission, consisting of persons generally conversant in, 1, examination of the physical condition of children; 2, mental condition of children; 3, education, and methods of dealing with children; 4, statistical compilation of facts; whose duty it should be to inquire into the condition of children in schools and elsewhere, and carry out the same upon a fixed plan. This Congress empowers the commission to add to their number, and to appeal to recognized authorities or sources for assistance if necessary."

The next paper was on "The Education of the Blind," and was by Dr. Campbell, Principal of the Royal College for the Blind. At its close the author proposed a resolution which was subsequently passed in the following amended form: "That the time has come when the blind, deaf, and dumb should have a well-graded, practical, and comprehensive course of instruction; that the training of the blind, deaf, and dumb should not be conducted on a charitable basis, but formed on a national system of education."

SECTION ON CHEMISTRY AND PHYSICS IN RELATION TO HYGIENE.

Meteorology in Relation to Hygiene.—Dr. Buchan read a paper on this subject. The author said he thought no city could be compared with London as affording the best available material for an inquiry into the relation of weather to health. He found the highest mortality occurred during the months of lowest temperature. He also noticed that the death-rate rose in proportion to the density and persistency of the fog.

Dr. Russell remarked that when there was a great increase of death-rate in foggy weather a low temperature accompanied the fog, but that there were dense fogs without decrease of temperature, and then the death-rate did not fall below the average.

Dr. Longstaff observed that meteorological curves and curves of death could not correspond exactly, owing to the fact that the interval between the death and its registration averaged about five days, and the interval between the commencement of an illness and a resultant death was of uncertain, often considerable, duration. He thought that meteorological changes were not of themselves the cause of death, though the number of deaths appeared to be contributed to by these changes.

Dr. Tripe said the effects of fog varied very much, according to their density and quality.

Dr. North drew attention to curves drawn by Professor Tacchini, showing the relation between the rainfall in the months of March, April, and May and the number of cases of fever in the province of Rome in the autumn. As the result of his own experience in the Roman Campagna, he entertained grave doubts as to the possibility of explaining the phenomena of intermittent fever on the hypothesis of a pathogenic organism.

SECTION ON STATE HYGIENE.

Several papers were read on the subject of the "Notification of Infectious Diseases." Considerable discussion ensued and the following resolution was carried by a large majority: "That notification of infectious diseases in all countries should be compulsory."

Papers on the "Prevention of Venereal Disease" were read by Dr. Birkbeck Nevins, and Mr. J. Holroyde. Several papers on the "Need for Popular Instruction in Hygiene in Schools" were read, and one on "Popular Instruction in Preventive Dentistry," by Mr. George Cunningham, of Cambridge.

In the Division of Demography, Colonel Woodhull, of the U. S. Army, read a paper prepared by Colonel Charles R. Greenleaf and Major Smart, of the U. S.

Army, on "Personal Identification by Scars, Marks, etc." (see p. 204).

The President of the Section, Mr. Galton, F.R.S., read a paper on "The Exhibition of Finger Prints, and of Registers of them as a Means of Personal Identification."

Dr. Bertillon gave an account of the anthropometrical method of identification of criminals, etc., worked out by his brother, Dr. Alphonse Bertillon.

Dr. Francis Warner read a paper on "The Physical Condition of Children Seen in Schools and the Local Distribution of Conditions of Local Development." In this paper Dr. Warner gave an account of fifty thousand children whom he examined for a joint committee of the British Medical Association and the Charity Organization Society.

A paper by Messrs. J. S. Turner and N. B. Paterson followed, on the "Examination of the Teeth of School Children," and the last paper was by Miss Fanny Fowke, on "The Physical Condition of Pauper Children Boarded out Under Local Government Board Orders."

A discussion followed the reading of these three papers. The following resolution was carried unanimously: "That an investigation which has been made in regard to the conditions of bodily development and brain action in some fifty thousand children indicates new and grave problems respecting the provisions necessary for the care and training of those who are more or less defective in make, and also respecting the causation, in certain districts, of maldevelopments which are much associated with defects of the brain, and that an extended scientific inquiry is desirable for the further elucidation of the subject."

Therapeutic Hints.

Thuya Occidentalis in Urinary Incontinence.—Dr. Howe, of Cincinnati, writes: "The enuresis of childhood and the urinary incontinence of old age, unless the dribbling be from paralysis, are generally suppressed by the use of a carefully prepared tincture of thuya. The drug should be prepared pharmaceutically with little alcohol, and the chlorophyll should be extracted as far as practicable."

Senile Pruritus.—Dr. Besnier, writing in *l'Union Médicale*, recommends the following method for the relief of pruritus in the aged: Every evening the body is sponged with a lotion, warmed to 104°F., to each quart of which is added one ounce of a solution of one part of carbolic acid in fifty parts of aromatic vinegar. After drying the parts are powdered with one of the following: Salicylate of bismuth, ʒ v.; powdered starch, ʒ iij, or finely pulverized salicylic acid, ʒ ijss.; powdered starch, ʒ iij. Bran or starch baths are also recommended.

Gonorrhœa.—Castelan claims to have had excellent results in the treatment of acute gonorrhœa by injections of a one per cent. solution of bicarbonate of soda.

For Eczema.—

℞. Thymol ..... ʒ ss.
Oxide of zinc,
Starch ..... āā ʒ vj.
Lard ..... ʒ jss.
M. Sig.: Apply twice a day to the affected parts.

—*Journal des Maladies Cutanées et Syphilitiques.*

Thuya for Aphthæ.—Dr. Howe, of Cincinnati, recommends a mouth wash and gargle of thuya in aphthæ and in mucous patches of the mouth and fauces, and says that no other remedial agent does as well.

Chaulmoogra-oil in Leprosy.—In the report of the Trinidad Leper Asylum for 1890, Dr. W. V. M. Koch says that the action of chaulmoogra-oil in reducing anæsthesia and causing the absorption of tubercles in leprosy is very uncertain, but that the physical condition of the patient improves greatly under its use. It has a very good effect in allaying the neuralgic pains in the joints and in promoting the cicatrization of ulcers. It is given in doses of ten minims, rapidly increased to thirty, three times a day, but sometimes must be discontinued by reason of the nausea it occasions. Its use should be continued if possible for long periods of time, in order to obtain good results, and when its administration by the stomach is not tolerated inunctions may be resorted to.

Diphtheria.—Dr. Joseph Burghardt, of Vienna, uses a powder of equal parts of washed sulphur and sulphate of quinine, applied very thoroughly to the pharyngeal walls by means of a powder-blower. In a lecture on this subject, translated by Charles Raettig, the author claims never to have lost a patient from diphtheria since he began to employ this method, having had thirty-three consecutive recoveries of patients from one to twenty-five years of age.

To Check Vomiting in Cholera Infantum.—Dr. N. Mandelstamm, of this city, writes: "It is well known that occasionally the usual remedies fail to control the vomiting in cases of gastro-intestinal catarrh in children. In such cases I have used moschus orientalis for several years while in Europe, and have been very well satisfied with its action. I have seen some cases in which the vomiting was at once stopped by the musk, while the diarrhœa was uninfluenced by it. Of how great importance it is for the nourishment of the child to stop the vomiting, it is needless to say. The most convenient formula for the administration of the remedy in these cases I have found to be the following:

℞. Tincture of musk ..... ℥xx.
Red wine (may be omitted) ..... ʒ ss.
Simple syrup ..... ʒ ss.
Infusion of salep ..... grm. ij.
M. Sig.: A teaspoonful every two hours."

Wocher's Method of Reducing Subcoracoid Dislocations of the Humerus.—Dr. E. S. Cleveland, of Burlington, Kan., writes: "I did not have an opportunity to test this method, to which attention was called in the Medical Record a year or more ago, until recently, when I was called to a case of the kind within a few moments after the injury was received. Though there was very little relaxation, I thought best to make trial of the method without chloroform, and the reduction was so easy and perfect as to surprise me. If this case is a sample of the method, it should be used in preference to any other. The movements were as follows, the patient being on his back on the floor, and the opposite shoulder being held down firmly: 1. Adduct the arm to the body, and draw down the elbow flexed to a right angle. 2. Rotate outwardly till the forearm touches the floor. 3. Maintaining the external rotation, carry the elbow to the sternum. 4. Place the hand upon the opposite shoulder. The whole process did not occupy more than half a minute."

To Remove Superfluous Hair.—Dr. Frank Van Allen, of Madura, India, writes: "By means of the following method I have cured two fairly severe cases of hirsuties of the upper lip:

℞. Powdered air-slaked lime ..... ʒ j.
Orpiment (arsenic trisulphide, As_2S_3) ..... gr. ij.

Add water enough to form a paste, and mix. Apply to the hairy surface about a quarter of an inch thick. Allow the paste to remain for fifteen or twenty minutes, when it will be dry. Remove; and the surface which before was hairy will be as smooth as the palm of one's hand, the hair coming off with the paste. The skin may or may not be slightly reddened, but this redness will pass away within an hour or so. After a few days the eaten-off ends of the hairs will be seen on careful examination, but a second application of the paste will as before destroy the hair. These applications will have to be made about twice a week at first, then once a week, then once a month, etc. The hair grows out at first

very much as if it had been merely shaved off; later, on careful examination, each individual hair is found to be thinner than before, growing less strongly, the hair, if black, losing its color, and, in a word, yielding to the continual irritation of the paste. This treatment requires about a year or a year and a half to effect an entire cure, but it possesses the advantage that immediately after the first application the patient is, as far as all outward looks go, completely relieved of her deformity. The most practicable way to direct the patient in the preparation of the paste is to tell her first to provide herself with a small mortar and pestle. Put into the mortar as much of the lime powder as can be held on the end of a spatula or table-knife. Add a few drops of water and mix to a paste. Then with the moistened end of the pestle dip lightly into the powdered orpiment, so that about as much orpiment as would altogether equal a pea in amount clings to the pestle. Mix this with the lime. Do not use too much orpiment. Apply at once. All samples of orpiment do not work well, and on becoming acquainted with this method, some three years ago, I tried five or six samples before I finally procured one that gave good results."

Persulphate of Iron in Dysentery.—Dr. W. Stuart Leech, of Morristown, Tenn., writes: "Two cases of dysentery of great severity recently came under my observation. Both cases were almost identical in onset and recovery, and followed one after the other with the usual dysenteric symptoms. The evacuations consisted of pus, blood, and real blood-clots, and their frequency had reached in one case to thirty five, and in the other to forty-two, during the twenty-four hours. The small, quick and feeble pulse, and anxious expression of the face, with the great amount of blood discharged, indicated a fatal termination. Double doses of opium and astringents were given, with little or no effect. Following a suggestion of my friend, Dr. Millingan, I injected in the rectum, with an ordinary rectal syringe, a solution of ferri persulphas. Its action was like magic, the bloody stools and other symptoms at once disappearing Only one injection was given in each case, and on the third day from that time both cases were dismissed. I wish some of your readers would tell me if this treatment is novel or not. I can find no objections to its use."

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 6, 1891, to September 12, 1891.

HORTON, SAMUEL M., Major and Surgeon. Relieved from further duty at Fort Adams, R. I., and will proceed to San Diego, Cal., and report to the commanding officer for duty at that post.

MIDDLETON, J. V. D., Surgeon. Granted leave of absence for fifteen days.

KIMBALL, JAMES P., Major and Surgeon. Granted leave of absence for twenty-five days.

HUNTINGTON, DAVID L., Surgeon. Leave of absence extended to include September 30, 1891.

HEIZMANN, CHARLES L., Surgeon. Relieved from duty at Fort Clark, Tex., and ordered to Fort Douglas, Utah, relieving Surgeon William D. Wolverton.

WOLVERTON, WILLIAM D., Surgeon. Upon being relieved, will proceed to Fort Schuyler, N. Y., and report for duty at that station.

HUNTINGTON, DAVID L., Surgeon; MCELDERRY, HENRY, Surgeon; REED, WALTER, Assistant Surgeon; GANDY, CHARLES M., Assistant Surgeon. Appointed members of a Board of Medical Officers to meet in New York City, October 1, 1891, for examination of candidates for admission into the Medical Corps of the Army.

CRAMPTON, L. W., Captain and Assistant Surgeon. Granted leave of absence for fifteen days.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 12, 1891.

WELLS, HOWARD, Surgeon. Ordered to temporary duty in the Bureau of Medicine and Surgery.

DICKSON, S. H., Surgeon. Detached from the practice-ship Constellation and await orders.

CURTIS, L. W., Passed Assistant Surgeon. Detached from the practice ship Constellation and ordered to the Naval Academy.

RUSH, W. H., Passed Assistant Surgeon. Ordered to the Yantic.

BEYER, H. G., Passed Assistant Surgeon. Detached from the Yantic and granted two months' leave.

BOYD, ROBERT, Assistant Surgeon. Detached from the Dale and ordered to the Marine Rendezvous, Boston.

WELLS, HOWARD, Surgeon. Ordered to special duty in fitting out the new Naval Hospital at Portsmouth, N. H.

HALL, JOHN H., Surgeon. Ordered before the Retiring Board, September 19th.

ROSS, JOHN W., Surgeon. Ordered, in connection with present duty, member of Board on Labor Employment.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 12, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	42	9
Scarlet fever	50	17
Cerebro-spinal meningitis	3	6
Measles	24	1
Diphtheria	80	21
Small-pox	1	0
Varicella	0	0
Pertussis	0	5
Erysipelas	1	0
Mumps	1	0
Rötheln	0	0

Cremation in Tokio.—The *Sei-I-Kwai Medical Journal* of February 28, 1891, publishes a table of the number of cremations in the six crematories in Tokio during the two and a half years ending June 30, 1890, from which we learn that there were 11,036 cremations during 1888, 12,405 in 1889, and 5,572 for the first half of 1890.

The Kapillarhebermikroskopirtropfenflasche is the name of an apparatus for dropping fluid used in microscopical work, described by Professor M. W. Beyerinck in the *Centralblatt für Bakteriologie und Parasitenkunde*. The author is, however, not obstinate in his partiality for the name, and obligingly proposes Kapillarheberbakterienkulturkölbchen as a substitute for those who think the other is too long.

A Pharmacist's Mistake.—A physician in Mans who was attending a child with bronchitis ordered some apomorphine for hypodermic injection. A pharmacist put up the prescription and the injection was given, but instead of vomiting the child became comatose and died. The druggist said that he had no apomorphine and so put up muriate of morphine, thinking that the effect would be the same. His homicidal act was punished with only three months of imprisonment.

Congress of American Physicians and Surgeons.

Second Triennial Meeting. Held at Washington, D. C., September 22, 23, 24, and 25, 1891.

First Day, Tuesday, September 22d.

The meeting was called to order at three o'clock, and Dr. Pepper, of Philadelphia, with a few appropriate remarks, introduced Dr. S. Weir Mitchell as President of the Congress.

The Conditions Underlying the Infection of Wounds.—The subject announced for the discussion of the afternoon was "The Conditions Underlying the Infection of Wounds," including a discussion of disinfection with reference to the treatment of wounds, of the relation of bacteria to suppuration, of the resistance of tissues to the multiplication of bacteria, and of the effects of antiseptic agents on wounds.

Dr. William H. Welch, of Baltimore, opened the discussion. The first, and comparatively simple, idea concerning the infection of wounds by bacteria, much in the same way as meat-broth was rendered putrid by the introduction of these organisms, the speaker said, had given way to much more complex problems, and it was the province of his paper to discuss some of those questions which had grown out of the modern study of bacteriology.

Observations which he had made showed that a white staphylococcus, formerly classified as the staphylococcus pyogenes albus, was frequently present in stitch abscesses and was very commonly found in the epidermis. Another bacterium very commonly found in intestinal disease, is the colon bacillus. Fraenkel has recently reported the presence of a pure culture of this bacillus in nine out of thirty-one cases of peritonitis, and the speaker had himself found it on several occasions in wounds which had been treated aseptically. In these cases there was moderate fever, and a thin, brownish, non-purulent discharge from the wound. It is difficult to account for the presence of the same pyogenic coccus in an insignificant pustule, in a dangerous phlegmon, and in an ulcerative endocarditis. Nor is the quantity necessary to produce suppurative inflammation the same for all parts of the body. Undoubtedly, a partial explanation of these differences is to be found in the rapidity of absorption in different localities, and in the presence or absence of additional toxic substances. Human tissues appear to respond more readily to inoculation with pyogenic cocci. Various conditions in and about a wound predispose to infection. Thus, the source, number, and virulence of the micrococci, the locality of the wound, the presence of drainage-tubes, and the handling to which the tissues have been subjected, all exert a modifying influence. Although contact-infection is the most to be feared, it is unwise to ignore the danger of air-infection, and hence more attention should be paid to the purity of the air in an operating-room and its freedom from dust. Many chemical substances predispose to infection by acting as irritants, and this is notably the case with corrosive sublimate, which Halsted has shown may produce an area of superficial necrosis, visible under the microscope, when employed in as weak solutions as 1 to 20,000. Bacteriological experiments show that in healing by blood-clot there is no danger from the presence of the clot. It is especially interesting to note that the author's experiments have elicited the fact that the white staphylococcus exists in the deeper layers of the skin, and is capable of resisting all known methods for cleansing the skin. On this account Dr. Halsted has for the past two years abandoned the use of skin sutures, using in their place subcutaneous ones, and his results have been most gratifying.

Dr. Roswell Park, of Buffalo, continued the discussion on wound infection, a subject which he considered inseparable from that of immunity. The condition called sepsis is a most complicated one, consisting as it does of a poisoning by ptomaïnes, toxines, and albumoses, having widely varying strength and properties. Various poisons are formed in the alimentary canal, and physiology teaches us that the liver filters them out before they reach the systemic circulation.

The speaker had on a previous occasion endeavored to show the importance of this hepatic function in the avoidance of septic intoxication in surgical patients. It is important to bear in mind, in connection with the general subject of blood-poisoning, that intestinal toxæmia, or entero-sepsis, was of frequent occurrence, and deserved a prominent place. In this connection it is interesting to recall the excellent results obtained in various septic conditions by the administration of a purgative, which stimulates the liver and frees the alimentary canal from toxic materials.

In the study of wound infection and of immunity, one is called upon to investigate the antagonisms of different bacteria, and the poisons which they produce. Pfeffer has given the name chemotaxis to that faculty possessed by all motile bacteria of moving toward or away from certain substances which seem to attract or repel them. This faculty is, however, not confined to bacteria, for the leucocytes possess powerful chemotactic properties, and the albuminoid material furnished by bacterial cells seems to offer the most attraction for these leucocytes. It is this that attracts leucocytes to an infected area. Whether living or dead, bacteria seem to attract toward them leucocytes, which act as scavengers for the surrounding tissues. In the light of our present knowledge, it is difficult to see how the possibility of phagocytosis can be denied. According to this doctrine, then, in both suppuration and absorption the leucocytes are attracted by the proteid material furnished either by bacteria or by disintegrating tissue suffering from other infection. Applying this knowledge to practice, it is easy to understand, how, in the separation and absorption of large sloughs, this chemotaxis results in bringing large numbers of leucocytes where they are needed for tissue repair. This subject suggests another practical thought, worthy of careful study, viz.: the chemotactic activities of the antiseptics in common use.

It must not be forgotten that by no means all the sources of sepsis concern the wound itself; the other principal sources may be classified as follows: 1. Previous long-existent toxæmia, *e.g.*, syphilis, diabetes, acetonæmia, lithæmia, alcoholism, malaria. 2. Previous anatomical changes which reduce vitality, *e.g.*, inherited diatheses, old age, amyloid change, chronic and acute nephritis. 3. Recent or acute toxæmia, *e.g.*, uræmia, typhoid intestinal toxæmia, stercoral toxæmia. 4. Other acute conditions, *e.g.*, starvation, scurvy, anæmia. 5. Conditions of environment—bad hygienic surroundings. 6. Effect of anæsthetics. 7. Effect of antiseptics.

The speaker laid great stress upon the importance of

intestinal toxæmia, for he had frequently seen commencing septic disturbance in wounds of all parts of the body quickly aborted by clearing out the alimentary canal.

In regard to the effect of antiseptics, it seems at first glance absurd to suppose that they may actually favor infection, yet not infrequently the patient is so poisoned by these substances that his cell-resistance is diminished or destroyed, and consequently there is little or no opposition to infection. Again, the chemical reaction occurring between the antiseptic agent and the vital fluid may be such as to destroy the properties of the former, and at the same time so change the tissues as to favor rather than resist infection. These observations apply with especial force to the action of corrosive sublimate solutions. Numerous experiments have shown the high value of blood serum as an antiseptic, and it is probable that further study will teach us how to utilize this most important property to the best advantage. At present the ideal antiseptic would seem to be the peroxide of hydrogen, which not merely destroys living organisms, but, by oxidation of infected material, acts as a scavenger of the tissues.

After enumerating the principal sources of contact-infection, the speaker gave brief directions concerning the best methods of avoiding such infection. For sterilizing the skin, where time would allow of elaborate preparation, he advocated shaving; the application for a day or two of some antiseptic ointment; again washing, using the sapo viride of the German Pharmacopœia with five per cent. of lysol or of hydro-naphthol; next the use of compresses, moistened with some liquid, non-irritating antiseptic, like a creolin, or hydro-naphthol, and finally, another shaving and scrubbing with hydro-naphthol soap, and a last washing with equal parts of alcohol and ether. The instruments are best prepared by subjecting them, in a dry sterilizer, for half an hour to a temperature of 140° to 150° C. Sponges may be rendered aseptic by the methods now in vogue, but it is better in most instances to discard them for some other cheap absorbent material, which can be used once and thrown away. Silk sutures should be wound on glass spools, and placed in a glass tube, and then kept for an hour in a steam sterilizer upon two different occasions. Raw catgut should be deprived of its fatty material by immersion in benzine or ether, after which it is dried and then soaked for two days in a one per cent. watery solution of corrosive sublimate; it is next dried and transferred, first to the oil of juniper berries, and then to a one in one thousand solution of sublimate in alcohol. If it be desirable to chromicize it, this may be done before it is placed in the juniper oil. The method prescribed for cleansing the hands and arms is quite elaborate, nevertheless it is so effective that there need be no fear of contaminating a wound, even though the operator has just come from demonstrating on the cadaver. They should be first washed with a nail-brush, soap, and water, then with a tablespoonful of mustard-flour, which is both a deodorizer and an antiseptic, next a thorough rubbing with the sapo viride containing five per cent. of lysol, creolin, or hydro-naphthol, after which they should be rinsed and immersed in a strongly colored solution of permanganate of potassium. After another rinsing the skin is decolorized with a solution of oxalic acid, and the toilet completed by a final rinsing in water. Regarding drainage, it may be said that it is now considered unnecessary, and a confession of fear, except in infected cases. Any sterilized absorbent material will answer for a dressing, and with the exception of cases in which the dressings are to be saturated with wound discharges, they need not be charged with an antiseptic.

The following are some of the author's conclusions:

The surgery of the future must aim to be aseptic, for, so far as fresh cases are concerned, we have passed the merely antiseptic era.

Asepsis is to be achieved not only by attention to the wound and the paraphernalia of operation, but by the closest regard to the condition of the patient's organs and tissues.

Sepsis and infection are combated in various ways by the inherent properties of cells and fluids, and the wisest man is he who studies to take advantage of these vital activities, rather than introduce new and conflicting elements from without.

Entero-sepsis, or stercoral intoxication, is a condition which every practitioner should fear, and against which he should assiduously guard. When perfect asepsis has been secured, the use of drains or the further employment of antiseptics is an expression of mental uncertainty or of fear.

Dr. Arthur T. Cabot spoke of the bearing of modern bacteriology on the practise of surgery. Lister and his immediate followers endeavored only to shut out bacteria from wound surfaces, but in doing so they found that septicæmia, erysipelas, and similar febrile conditions were almost completely banished from hospitals in which they had hitherto been prevalent. Gradually the truth dawned upon them that the tissues were not mere passive breeding-places for bacteria, but that within certain limits the tissues were able to successfully combat the bacteria introduced into wounds. Numerous experiments have shown that fresh blood-serum is bactericidal, and this is supposed to be due to a special ferment. The speaker said that he had a number of times made cultures from the skin immediately before and after operation, and had found invariably that, notwithstanding the field of operation was absolutely aseptic before operation, it did not remain so during the operation.

Mr. Thomas Bryant, of London, said that while the papers which had been presented were difficult to discuss, they were of much interest to the practical surgeon. It must not, however, be forgotten that if the bacteria form seed, the soil must not be less important, and if present theories are correct one cannot but wonder that any of the patients of former times have recovered. He was glad to have the opportunity to still further emphasize the great importance of the preparatory treatment of the patient—in other words, the preparation of the soil. Many of the antiseptic measures of the present day were, in his opinion, unnecessary. Personally, he believed in occasional irrigation, and the fluid which he had used with great satisfaction for the last twenty years was iodine water of a light sherry color. His plan is to dust the wound with one part of iodol to four of boracic acid, with the idea of preserving the wound from infection during the first twenty-four or forty-eight hours. The accumulation of fluid during this period makes it almost necessary to employ drainage, but by this he did not mean the passage of a large tube entirely through the wound.

Dr. Harold Ernst spoke of the relation of bacteria to suppuration, and referred more particularly to the influence of certain chemical substances upon chemotaxis.

Mr. Chiene, of Edinburgh, said that it had been his privilege to assist Lister for many years in his hospital work, and he felt more and more impressed with the great importance of the good work begun by Lister. He could corroborate everything that had been said by Dr. Park, and he thought the subjects discussed in the opening papers showed the benefits conferred upon practical surgeons by laboratory research. Lister long ago pointed out the antiseptic value of the blood-clot, but it might surprise many to hear that old John Hunter first pointed out its value. He regretted, therefore, to hear it spoken of as Schede's method. He was very sorry that the fashion of the times compelled him to abandon the spray, the more so because he had just learned that bacteria in the deep layer of the skin could not be destroyed. If these should come to the surface during an operation, how convenient it would be to have the spray at hand, to render them at once inert!

Dr. Arpad G. Gerster, of New York, remarked that although Hunter may have been the first to speak of healing by blood-clot, it still remained for Schede to re-

vive the subject and put it into actual practice. Speaking of contact infection, he had been impressed with the many ludicrous little habits of operators, such as scratching the head, rubbing the nose, and putting the scalpel between the lips, all of which did much to neutralize the effect of the many antiseptic precautions which had been carried out with the greatest minuteness. The crucial test of a surgeon's methods, was the occurrence of primary union without the slightest suppuration. Blunt dissection in loose areolar tissue was responsible for much needless injury of the parts, and should be condemned. While the abandonment of drainage and of the application of antiseptics to the wound is in accordance with our present knowledge, it is so difficult in practice to secure strict asepsis that it is unwise and premature to teach such a method.

AMERICAN SURGICAL ASSOCIATION.

Twelfth Annual Meeting, held in the Grand Army Building, Washington, D. C., September 22, 23, 24, and 25, 1891.

FIRST DAY, TUESDAY, SEPTEMBER 22D.

President's Address.—The Association was called to order by the President, DR. CLAUDIUS H. MASTIN, of Mobile, Ala., who delivered the President's Address. He referred to the foundation of the Association in 1879, during the meeting of the American Medical Association, at Atlanta, Ga., and paid an eloquent tribute to the memory of the founder, Dr. Samuel D. Gross. The first meeting of the new Society was held at Coney Island, N. Y., in September, 1881. The meetings were at first held in different cities in successive years, but in 1884 Washington was chosen as the permanent home of the Association. The speaker maintained that there was nothing antagonistic between this Society and the American Medical Association, and said that the fears of some that the one would detract from the efficiency of the other had proved to be unfounded. He called attention to the share that Americans had had in promoting the advance of surgical science, and then spoke of the benefit the Association had been to each of its members, mentioning incidentally that during the ten years of its existence there had never been the slightest breach of harmony among the members. In concluding, the speaker suggested that the medical profession of America should unite in raising a monument in marble or bronze to the memory of Dr. Gross, this statue to be erected in the city of Washington.

Present Status of Brain Surgery, Based on the Practice of Philadelphia Surgeons.—DR. D. HAYES AGNEW, of Philadelphia, read a paper with this title, of which the following is an abstract: What is the present position of brain surgery, and what practical lessons can be deduced from a review of the recorded results in this department of surgery? The object of the author was not to glean the entire field, but to confine himself to the work done by Philadelphia surgeons in trephining for epilepsy, traumatic and Jacksonian, intra-cranial abscess, hemorrhage, hydrocephalus, cephalalgia, microcephalus, and neoplasms.

Traumatic Epilepsy.—Fifty-seven cases were recorded. Of this number forty-one recovered from the operation, four died, and of twelve the result is not given. Thirty-two experienced temporary relief, nine obtained no benefit, four passed out of observation, four were operated on too recently to permit of the result being determined, and four are reported cured. In one of the cases reported cured the patient has been free from attacks for twenty-eight months, in two for ten months, and in the fourth a branch of the great occipital nerve was found impressed in the bone cicatrix. While the results in these cases have not been satisfactory, it by no means follows that surgery holds out no hope against epilepsy. It is not saying too much to assume that surgery is responsible for the great majority of traumatic epileptics, though this statement does not by any means criminate the surgeon of an early day. Whenever the profession can accept the doctrine that all depressed fractures, however slight the depression and entirely irrespective of pressure symptoms, are proper subjects for trephining, then will traumatic epilepsy largely disappear from the list of surgical diseases. It is not improbable, in view of the greatly diminished risk of trephining, that the operation will be extended even to cases of simple fracture or fissure of the skull.

Jacksonian Epilepsy.—The table contains fourteen cases. In all the discharging centre was removed. Nine recovered, and four died. Of those recovering, three had less frequent and less violent attacks, one realized slight benefit, one disappeared shortly after operation, and in two no benefit was observed. One is reported as cured, and in that case the operation was done during the present year.

Abscess.— Eighteen cases of this nature have been collected. Six had had fracture of the skull, two had syphilitic necrosis, in one a foreign body had entered the brain, in nine the abscess was due to middle-ear disease, and in two there had been a severe blow without fracture of the skull. All the patients died in less than fourteen days.

Five cases of trephining for intracranial traumatic hemorrhage are recorded, in each instance the symptoms necessitating operation developed within twelve hours after the reception of the injury. Four of the five cases recovered not only from the operation, but with the restoration of the suspended functions. Of trephining for acute and chronic hydrocephalus five cases are reported. All the cases died, one living to the forty fifth day. As hydrocephalus is usually due to tubercular disease or to morbid growth, it is difficult to understand on what ground such operations are undertaken.

Cephalalgia.—Five cases are given, in each of which the focus of pain was referred to the neighborhood of a scar on the scalp. In four of the cases complete relief was afforded.

Trephining for Microcephalus.—Seven cases are reported, of which four died and three recovered from the operation. One of the deaths, however, was due to scarlet fever occurring shortly after the operation. The result in the successful cases is reported as "moderate improvement." From the results obtained from the education of idiots, the author thought it wiser to relegate these unfortunates to special training-schools rather than to the trephine and rongeur. The debatable cases would be those accompanied with athetosis, in which condition some improvement might be obtained.

Brain Tumors.—Only four operations for brain tumors have been done by Philadelphia surgeons. In one the growth was a fibroma weighing four ounces. The operation was done by Dr. Keen, December 15, 1887, since which time the patient has had only six epileptic seizures. In the second case, done by the same operator, the tumor was in the occipital lobe and not removable. The patient died the following day from shock and hemorrhage. In the third case no tumor was found, and in the fourth a cyst occupying the cuneus was found and emptied. The patient died in thirty-six hours, and at the autopsy a large sarcoma was found occupying the temporo-sphenoidal lobe.

The deductions presented by the author are as follows: 1. That all fractures of the skull attended with depression, however slight, and entirely irrespective of symptoms, should, in view of the late after-effects, be subjected to the trephine. 2. That trephining for traumatic epilepsy promises only palliation at best. 3. That trephining for Jacksonian epilepsy is to be regarded as only affording temporary benefit. 4. That trephining for abscess, in view of the fact that all such cases left alone almost invariably terminate fatally, is entirely proper, and that the earlier such operation is done the better. 5.

That trephining for intracranial traumatic hemorrhage is both an imperative and highly promising operation. 6. That trephining for cephalalgia, or traumatic epilepsy (medical measures having failed), should be undertaken with every prospect of success. 7. That trephining for hydrocephalus is a useless operation. 8. That trephining for microcephalus, independent of athetosis, confers no credit upon surgery. 9. That it is more than probable that as our observations multiply the sphere of the trephine as a preliminary for the removal of brain tumors will be lessened rather than be amplified.

Dr. John Chiene, of Edinburgh, did not take the same depressing view in regard to traumatic epilepsy. He referred to three cases in which decided benefit had followed operation. He agreed fully with what had been said in regard to operation in depressed fracture whether or no symptoms be present. As regards methods, he spoke of simple measures for locating the fissure of Rolando. The upper extremity may be located by means of a piece of string hung one-half inch behind the middle. The angle may be severed by folding a square piece of paper into four around one of the angles. Three of these parts will give the proper angle. The purification of the scalp is a difficult matter, but may be accomplished by shaving and soaking with carbolic lotion for three days. For opening the skull he advised as safer than the trephine, the gouge and mallet. For enlarging the opening the gouge forceps fill a useful purpose. For puncturing the dura and the brain he uses a Graefe knife. Hemorrhage from the bone may be checked by plugging with a match; bleeding from the brain by hot water. Stress was laid upon the necessity of constant watching of brain cases and illustrative cases cited. In one case of supposed injury to the head (but which later proved to be a case of apoplexy), in which the patient was in a dying condition, great improvement, eventuating in practical recovery, followed trephining.

Dr. W. W. Keen held that every case of depressed fracture should be operated upon, even in young children. A blow upon the head not sufficient to cause fracture may produce laceration of the dura or of the cortex. In regard to linear fracture, however, he was disposed not to accept the view that operation should be performed. In regard to tapping of the ventricles, he thought that further experience and an improved technique would lead to better results. In epilepsy, he suggested the use of the bromides after operation had been done. In many cases of brain tumor, where there is no hope of removing the growth, great comfort may be afforded the patient by removal of bone.

Dr. Charles B. Nancrede, of Ann Arbor, reported cases in which cure had followed operation for traumatic epilepsy, in one the cure was of ten years' duration. Often cases that are reported as failures soon after the operation prove to be cures when followed for a longer time. The operation removes only one of the elements that is causing the epilepsy. In speaking of these operations he stated that hemorrhage from the skull could be checked by forcing in the diploë. In regard to simple fissured fracture, he asked how the diagnosis could be made.

Dr. Roswell Park, of Buffalo, differed from the author as regards the results of operations for epilepsy. He had himself had cases in which decided benefit was afforded. In order to determine the effect, time must elapse, so that the epileptic habit may disappear. The operation removes the anatomical cause, but ordinary therapeutic measures are needed to counteract the secondary conditions. Reference was also made to the relief afforded in brain tumors, even where the removal of the growth was not contemplated. He reported two cases of craniotomy for microcephalus in which benefit had followed.

Dr. H. C. Wood, of Philadelphia, thought that we should wait before coming to any conclusion as to the result of treatment either medicinal or surgical. He referred to one case in which under medicinal treatment the attacks remained absent for seven years and then returned. He advised that in these cases, before the contemplated operation was performed, a mock operation should be done and the effect noted. He cited cases in which such measures had been followed by benefit.

Dr. J. J. Putnam, of Boston, thought that a simple, smooth, depressed fracture would not be likely to cause any symptoms. The irritation from a sharp spicule of bone probably will cause irritation. Probably the most important element in the causation of trouble is the results of the original injury to the cortex. The interstitial changes in the cortex take the form of sclerosis, and it seems *a priori* doubtful that removal of the bone would materially affect it. The operation may not prove indifferent, for the cicatrization of the incised bone may lead to harm.

Mr. Thomas Bryant, of London, had been much struck with the emphasis with which Professor Agnew had insisted upon the treatment to be followed in depressed fracture. As a practical rule he was disposed to agree with him, but there are certain exceptions; he did not think it wise to encourage practitioners to trephine and elevate every case of depressed fracture. He could recall many cases of depressed fracture, followed for years, in which no symptoms supervened. Depression of the lateral aspects of the skull are not so apt to be followed by symptoms as depression of the vault of the skull. From these remarks, he said, it would naturally follow that he disagreed with the observation that in every case of fissure of the skull operation should be done. He wished Dr. Agnew had gone more thoroughly into the reason for this statement. If there has been no brain symptoms, although the blow may have been sufficient cause for fracture, it would not be wise to insist that we should at once proceed to explore to see if there is fracture. It is better to wait and watch for symptoms, being ready to operate as soon as there is a suggestion of something wrong. Although the risk of exploratory operation may be slight, yet it must be admitted that it is attended with some danger.

Dr. D. Hayes Agnew, in traumatic epilepsy, did not condemn operation, but curative results should not be expected from it. Its result is only one of amelioration. He could not withdraw his statement made in the paper, for in many of the cases of traumatic epilepsy there had been no history of unconsciousness or other symptom. There has been a blow on the head, and many years later epilepsy has appeared. It is impossible to determine the condition of the internal table of the skull by inspection of the external table. He had seen a simple crack in the skull with the internal plate forced downward some distance.

A paper on "Resection of the Wrist," by Dr. Rafael Lavista, of Mexico City, Mexico, was presented and read by title.

Report of a Committee on the Results of Treatment of Simple Fracture of the Shaft of the Femur.—Dr. Stephen Smith, of New York, presented the report of this Committee. At the meeting of the American Surgical Association, held May 15, 1890, the following preamble and resolution were adopted:

Whereas, In the treatment of fractures of the shaft of the femur the question often arises as to what is a satisfactory result in a given case; therefore

Resolved, That a committee be appointed by the President, to report at the next meeting of the Association, what in their judgment under the methods of treatment should be considered as satisfactory results.

The question referred to your committee has an important bearing upon the jurisprudence of surgical practice. One of the most frequent causes of prosecution of surgeons is the alleged maltreatment of fractures of the femur.

The following circular was sent by the committee to the members, "What should be considered as a satisfac-

tory result (other than perfect union) in the treatment of a simple fracture of the shaft of the femur." The committee has reviewed the several questions raised and endeavored to secure a common ground on which the Association can take its position, and on which members can individually stand before the courts.

1. *Bony Union.*—The necessity of firm bony union does not admit of discussion. The amount of callus should not be taken as a criterion of the success of treatment.

2. *Relation of Long Axis of the Fragments.*—While it is the aim of the surgeon to restore the normal relation of the long axis of the fragments, yet it is generally impossible to secure exact apposition of the fractured surfaces, nor can the normal long axial line be restored with mathematical precision.

3. *Correspondence of the Anterior Surface of the Fragments.*—On this depends the position of the foot, the result of treatment to be satisfactory requires that the anterior surface should be in the same plane.

4. *Length of Limb.*—This was formerly regarded as the test of success of treatment, the records of the past show that shortening was the universal rule. The discovery of the natural discrepancy in the length of the lower limbs has considerably modified our estimate of this test. Ninety per cent. of healthy, uninjured persons have lower limbs of unequal length. In 35.8 per cent. the right limb is the longer; in 54.3 per cent. the left is the longer. If the amount of shortening does not exceed the average natural difference in the length of the limbs, viz., about half an inch, the result will be in accordance with the laws of nature in the conformation of the lower extremities. If the shortening does not exceed the extreme limit of difference in the lengths of the natural limbs, viz., about one inch, the result should be considered satisfactory. An unsatisfactory result as regards shortening exists only when the amount of shortening exceeds one inch.

5. *Lameness.*—This is a symptom of variable importance. Some will have a limp with one-fourth inch shortening, while others will not limp with half or one inch shortening. In many cases the limp disappears with time, or if it continues it is the result of careless habits of the patient.

6. *Restoration of Function.*—Essential to the function of the femur is strength of the femur at the seat of fracture, free and unimpeded action of the muscles, and proper motion of the knee joint. The determination of the degree of restoration of function cannot be made for at least one year after the cessation of treatment.

7. *Conditional Results.*—There is a class of cases in which our estimate of results must be based upon a careful study of the special circumstances connected with the treatment of each case. Results widely different from those already given must be regarded as satisfactory when we consider the circumstances under which the treatment is necessarily pursued. The treatment may have been conducted under circumstances in which it was impossible to secure proper apparatus, or the injury may have involved other parts so as to prevent the patient from taking the necessary position, or the patient may have suffered from delirium or other malady.

The following conclusions were presented: A satisfactory result has been obtained in the treatment of fracture of the shaft of the femur when: 1. Firm bony union exists. 2. The long axis of the lower fragment is either directly continuous with that of the upper fragment or the axes are on nearly parallel lines, thus preventing angular deformity. 3. The anterior surface of the lower fragment maintains nearly its normal relation to the plane of the upper fragment, thus preventing undue deviation of the foot from its normal position. 4. The length of the limb is either exactly equal to that of its fellow, or the degree of shortening falls within the limits found to exist in ninety per cent. of healthy limbs, viz., from one-eighth of an inch to one inch. 5. Lameness, if present, is not due to more than one inch of shortening. 6. The conditions attending the treatment prevent other results than those obtained.

AMERICAN NEUROLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at the Arlington Hotel, Washington, D. C., September 22, 23, and 24. 1891.

First Day, Tuesday, September 22d.

The President's Address was delivered by Dr. Wharton Sinkler. After giving a brief history of the organization he referred to the fact that the American Neurological Association was one of the earliest of the national associations to favor the formation of the Congress of American Physicians and Surgeons, and he thought that since its connection with that body it had grown in importance, and the membership had become more general throughout the country. He alluded to the death of Professor Westphal, one of the honorary members of the Association. He recommended that an effort be made to obtain each year papers from some of the foreign honorary and associate members, and concluded by giving a list of the books and papers on neurological subjects by the members during the past year. Since the last annual meeting twelve books and one hundred and seventy-seven papers have been published by the fellows of the society.

Acute Spinal Paralysis—Death on the Twelfth Day—Autopsy showing Transverse Cervical Myelitis.—Dr. Wharton Sinkler, of Philadelphia, read a paper with the above title, and reported a case which was of interest, because, while having the clinical history both of acute polio-myelitis anterior and of Landry's paralysis, the post-mortem results showed a transverse myelitis involving only the cervical portion of the cord.

The patient was a male, eighteen years of age, with good family history. After exposure to cold, in a few days he complained of general weakness, had fever, some pain in the back, and cramp-like pains in the legs. Some diarrhœa. Within four days there was loss of power in both legs, and partial paralysis in both upper extremities. There was temporary inability to void urine, and some difficulty in swallowing. The muscles of the trunk were also paralyzed; both knee-jerks absent; loss of most of the superficial reflexes. Sensation was unimpaired. No muscular pain or tenderness over the nerve-trunks. All muscles reacted to faradism. The patient gradually lost strength and died of respiratory paralysis on the twelfth day.

From a study of the clinical features of the case the diagnosis lay between acute multiple neuritis, acute myelitis, Landry's paralysis, and polio-myelitis anterior. The author thought it probable that in the early stages of polio myelitis there is a hyperæmia or inflammation of the cord in the affected areas, which is not confined to the anterior horns.

Polio-myelitis Acuta Adultorum.—Dr. W. C. Krauss, of Buffalo, presented the history of a case of this disease. Patient was forty-three years of age, and was always strong and healthy. Antecedent history was good. Both grandparents passed through severe attacks of measles, between the thirty-fifth and fortieth years. The father likewise had a severe attack when thirty-four years of age. Some members of patient's family had shown evidences of insanity. The patient had a severe attack of measles in his thirty-eighth year. He remained in poor health. In his fortieth year, after a few days of fever and pain in the neck, extending down the spine, he became paralyzed in the body and limbs. The head and neck only were capable of voluntary motion. There was no objective sensory disturbance. The extremities were cold and cyanotic. There was some improvement after three or four weeks. He examined patient nine months after onset of attack, and found all four extremities more or less paralyzed. The muscles of the back had regained power. There was

absence of faradic irritability in the paralyzed muscles. No sensory disturbance. There was atrophy, cyanosis, and œdema. All of the reflexes were absent. The author was not willing to admit that the measles was capable of precipitating a serious spinal lesion, but believed that when neuropathic or psycopathic tendencies are inherited all infectious diseases engender to a greater or lesser degree organic nervous affections. It is worthy of note that so little, if any, improvement took place after the subsidence of the general symptoms. The points of difference between the symptoms offered and those of acute anterior polio-myelitis caused him to hesitate before coming to a conclusion, and he believed that his diagnosis needs confirmation by a necropsy.

Dr. Charles K. Mills said the association of polio-myelitis with multiple neuritis was of comparatively frequent occurrence. There was a type of infantile paralysis of this description, and he had seen a case. The patient, seven years of age, had diphtheria, which was followed by an attack of sensitiveness over both lower extremities. Eventually there was paralysis of a group of muscles in one leg. He thought the question of infectious diseases causing multiple neuritis in association with polio-myelitis an interesting one. This was, however, more likely to occur as a result of various toxic agents. In a patient under his observation the paralysis was general, but recovery supervened. There was probably a combination of both lesions. He had years ago directed attention to this concurrence, particularly in arsenical poisoning.

Dr. R. T. Edes thought Dr. Mills's point a good one, but doubted if this concurrence is only confined to infectious diseases, but might also result from alcohol.

Dr. Knapp agreed with the preceding speaker. He had seen chronic neuritis in which there were signs of cord trouble. One case, observed many years, showed combination, but recovered.

Dr. Walton spoke of a case of multiple neuritis from lead, with atrophy, ataxia, etc., who died after spinal symptoms and cystitis. Absolute differentiation between spinal and peripheral lesions, owing to their co-existence, is sometimes unnecessary.

Dr. C. L. Dana disliked to have the impression go abroad that there is no definite lesion in these cases. In all cases of acute or subacute neuritis from alcohol, rheumatism, etc., the lesion was confined almost exclusively to the peripheral nerves. He has numerous specimens in his laboratory to substantiate this view in connection with the clinical histories. In cases of chronic neuritis he was not so positive.

Dr. C. H. Hughes believed that peripheral neuritis is a settled fact, and can generally be diagnosticated. He referred to our errors in earlier days, and was of the opinion that most cases of myelitis were due to exposure to cold, when not occasioned by traumatism. He agreed with Dr. Krauss in reference to the relation of measles to polio-myelitis. He believed all zymotic diseases frequently affected both the central and peripheral nervous systems.

Dr. E. D. Fisher referred to Charcot's work on poly-neuritis, and agreed with the previous speakers. He thought the combination more frequent than was supposed. He differed from Dr. Dana, but believed the changes in the cord may exist, but are not discoverable by our present means of examination.

Thomsen's Disease.—Dr. Walton then read a paper describing a typical case of Thomsen's disease. All muscles were affected, including the eyelids and muscles of deglutition. The patient was twenty-nine years of age, and the trouble had been stationary since his fifteenth year.

Dr. Angell, of Rochester, read the history of two similar cases.

Dr. Hughes maintained that Thomsen's disease is an affection of the muscular system, and doubted the entity of such a disease. Thinks it a peculiar form of symptomatic condition. It differs from every kind of spasm with which we are familiar.

Astasia-Abasia.—Dr. Knapp read a paper on this subject, and gave Blocq's definition of the affection as "a morbid state in which the impossibility of standing erect and walking normally is in contrast with the integrity of sensibility, of the muscular strength, and of the co-ordination of the other movements of the lower extremities." The author had collected forty-nine cases by various writers, and reported one under his care. The patient was fifty-eight years of age. Movements were made with fair strength while lying down. Spasm comes on suddenly and limbs get rigid. Physical examination negative. Tonic treatment was inefficacious. He subsequently developed retropulsion and resembled a case of paralysis agitans. Some difficulty in articulation and voluntary movement. Thinks the case may develop into paralysis agitans. The diagnosis is not always clear. The affection cannot be regarded as a morbid entity, but should be studied as a symptom complex. Best results are obtained by moral treatment and substitution of volitional for automatic movements.

Dr. G. M. Hammond thought that the way to show that the affection was not organic was that the patient could perform walking movements while recumbent. His case had not improved under various known methods of treatment. The only remedy he found of efficacy was bicycle riding, and his patient can now ride a bicycle. He considers the affection as one of the manifestations of hysteria.

Dr. Walton looked upon it as analogous to hysterical aphonia, etc. If not identical it is allied to it. He would not lay so much stress on the absence of stigmata of hysteria as Dr. Knapp. He had observed a case, and thought the prognosis no different from that of hysteria.

Dr. Dana wished to corroborate Dr. Knapp's suspicion of his case being one of paralysis agitans. He had a patient with abasia who was a manifest case of paralysis agitans. There was the peculiar gait and rigidity, and he was frequently obliged to stop suddenly while walking.

In paralysis agitans cases there is, however, no astasia. They are always able to stand.

Dr. Hughes said that older writers like Weir Mitchell and Charcot described these cases as hysteria. It has been left to modern neurology to show that hysteria may co-exist with organic disease. Blocq had found these cases in connection with the rheumatic condition. He thought hypnotism might prove of aid in diagnosis.

Dr. Bullard had a case of typical astasia-abasia without any other hysterical manifestations.

Dr. Knapp, in closing the discussion, said he wished to emphasize the fact that there was no actual loss of power.

AMERICAN GYNECOLOGICAL SOCIETY.

Sixteenth Annual Meeting, held at Washington, D.C., September 22, 23, and 24, 1891.

A. Reeves Jackson, M.D., of Chicago, Ill., President.

First Day, Tuesday, September 22d—Morning Session.

Address of Welcome.—Having thanked the society for the honor conferred upon him in electing him president, which he declared was undeserved, Dr. Jackson introduced Dr. Joseph Taber Johnson, of Washington, who read an address of welcome. In it he called attention to the advantages gained by a congress of medical societies, such as was now being held in the city, to the points of interest in the capital, and expressed the sorrow which he felt in common with the other members at the death of Dr. Barker.

The Advantages of Mixed Narcotics in Gynecological Surgery.—Dr. John R. Reeve, of Dayton, O., read the first scientific paper. By this method he meant preceding the anæsthetic by a hypodermic injection of mixed atropia and morphine. He had used this method

twenty years. Had never had a death, nor indeed serious symptom, under this form of hemorrhage. He summarized the advantages of the method as follows: 1. The emotional excitement was allayed. By the morphia dread and apprehension were made to disappear, the nervous system yielded readily and kindly to the anæsthetic. 2. The anæsthetic was more rapidly and steadily introduced, the stage of excitement being brief. 3. The feeling of suffocation during the administration of ether was much lessened. 4. Anæsthesia was not only more readily produced, but was far more steadily maintained. 5. Absolute quiet was a marked feature of the mixed method. 6. A period of quiet rest and freedom followed the operation. 7. Vomiting, so deleterious in many ways, was lessened. He had rarely seen a case of severe vomiting after mixed anæsthesia. He had succeeded in finding records of only three deaths during mixed anæsthesia, in one of these a dangerous amount of morphine having been injected.

Mention was made to the use of this method first by Nussbaum, to the experiments of Bernard, the physiological action of atropia and morphine, etc. The combination usually had been with chloroform, but the author used one-half ether.

Dr. Sawyer had employed the combination of morphine and atropia injection with chloroform inhalation in the second stage of labor with much satisfaction and relief of suffering.

Dr. Howard said that in the hospital with which he was connected, in Baltimore, they had given up the use of chloroform after having had three deaths from it. They now used ether, preceding with an injection of a solution which included atropia and morphine.

Dr. John Byrne, of Brooklyn, N. Y., used ether after injecting a solution of morphine and atropia, and where he had neglected the hypodermic injection his patients invariably suffered from the neglect, more ether was required, there was greater violence, severer vomiting, etc.

Accidental Hemorrhage Occurring During the First Stage of Labor at Term.—Dr. H. C. Coe, of New York, read the paper. Little had been added to our knowledge of the subject since the appearance of Goodell's paper, twenty years ago. It was the writer's purpose not to discuss the entire subject of accidental hemorrhage in the gravid womb, but simply that form which occurred during labor. This was not only the more infrequent but the more fatal form, and was rarely of traumatic origin. A case was recited.

Etiology.—The etiology was obscure. Predisposing causes were hemorrhagic diathesis, general febrile affections, renal troubles, death of the fœtus, hydramnios, diseases of the placenta. Irregular uterine contractions had been noticed in twenty per cent. of the cases. Undoubtedly in a certain number of the cases the cause was shortness or twisting of the cord. The accident could not be ascribed to a single etiological factor in a non-traumatic case. There was usually a combination of several.

Symptoms.—It was important to bear in mind that there were two sets of symptoms, initial and final. Most writers affirmed that the latter alone were reliable, and were recognizable too late for successful interference. But the writer believed it possible to detect accidental hemorrhage at its inception by careful attention to the initial phenomena, especially irregularity and feebleness of the labor pains. The patient complained of pain in the lower part of the abdomen which gradually grew worse and assumed a bursting character. External palpation might at first reveal nothing abnormal. Auscultation of the fœtal heart showed it feeble and irregular, showing the fœtus was being subjected to some serious disturbing influence. Patient restless, but able to sit up, pulse not affected. The ordinary observer might mistake the case for one of uterine inertia. These symptoms should lead one to suspect internal hemorrhage. External bleeding had been absent in three-fourths of the cases reported. The more advanced symptoms could readily be recognized.

Prognosis.—This was so bad that unusually favorable statistics led to the inference that the cases were not serious ones. In order to save mother and child, or even the mother alone, there must be a combination of favorable circumstances—skill and promptness of attendant, unusual resistance to shock, efficient treatment of the uterus after delivery. It should be assumed the child would perish, and all attention should be devoted to saving the mother.

Treatment.—There was much want of unanimity of opinion as to the treatment of these cases. Some advised immediate delivery, others delay. The writer disapproved of rupturing the membranes and administering ergot when there was no prospect of immediate delivery. It did not overcome the obstacle to delivery and might cause continuation of the hemorrhage. The writer's plan was: As soon as the accident was recognized to vigorously stimulate the patient by mouth, rectum, and hypodermatically while sending for aid. Under complete ether anæsthesia the os should be carefully dilated manually, Barnes's bags being only employed when the os was rigid and patient's condition such as to allow a certain amount of dilating. The membranes should be preserved intact. Perform version with unusual care. At this stage administer ergot freely by injection. A short delay before extraction in order to give the uterus time to recover its tone. If the head were engaged and the os could be readily dilated, the membranes should be ruptured at once and craniotomy performed instead of losing time to deliver with the forceps. The most important step was to prevent post partum hemorrhage. The hand should be introduced into the uterus, placenta and clots removed, and the cavity at once tamponed with iodoform gauze.

Dr. Charles Jewett mentioned the friability of the vessels and conditions which favored easy separation of the placenta or etiological factors in the causation of the severe hemorrhage mentioned in the paper. He thought an abdominal bandage might be of some service where the membranes were yet unruptured. Precipitate interference in bringing on labor had often hastened death by adding shock and perhaps further hemorrhage to the loss of blood which had already taken place. He also spoke of the value of tamponing by iodoform gauze in order to check hemorrhage of different forms in obstetric practice.

Dr. R. A. Murray had seen a few cases of severe hemorrhage before labor, which he referred to in emphasizing the fact that the treatment after dilatation of the os must differ from that which should be practised before. Dilatation not having occurred, he introduced an iodoform tampon, had the arteries of the upper and lower extremities compressed by assistants, feet elevated in order to drive the little blood left to the brain and keep up life when delivery did take place; a basin full of clots escaped. The patient lived. Had labor been induced hastily he was satisfied the patient could not have withstood the additional shock. Stimulants were also indicated.

Dr. Frey thought Porro's operation would be justified in cases in which the cervix was not yet dilated. It could hardly increase the present mortality-rate.

Dr. Raymond had seen in consultation one case which proved fatal immediately after delivery, in which a striking feature was extreme thinness of the entire uterine walls.

Dr. Skene facetiously suggested as prophylactic against these cases of hemorrhage removal of the ovaries.

Dr. T. Addis Emmet suggested inversion and ligation of the uterus.

The Therapeutic Aspect of Some Ovarian Disorders.—Dr. Edward W. Jenks, of Detroit, Mich., said it was his object, in writing a paper with this title, to direct attention to the merits and demerits of well-known modes

of treatment in certain ovarian diseases. He had in mind more especially surgical treatment, not excluding electrical. In general, the paper was a plea for more conservatism with regard to removal of the ovaries. Battey's operation was being done in every hamlet of the land, often by inexperienced physicians, who neither exercised judgment in the selection of cases, nor were prepared to give the patient the advantages of an operation skilfully and aseptically performed.

AFTERNOON SESSION.

Insanity Following Gynecological Operations.—DR. J. M. BALDY, of Philadelphia, read the paper. He had, by correspondence with physicians in the institutions for the insane in Pennsylvania, elicited the information that in eight (those making reply) there had been only fifteen cases of insanity in which laparotomy had been performed. In eleven of them there had been pre-existing insanity. Yet insanity following gynecological operations was more frequent than the figures would indicate. Many of the cases were mild and did not reach asylums; some of the more severe terminated quickly, as one of his cases, in which death took place about four days after the operation. He had had one other which recovered. His conclusions were: 1. That cases of serious mental derangement might occur after operation in a person without a family history of insanity. 2. That mental disorders were no more likely to follow operations on the sexual organs than on other parts of the body. 3. That the accident was as frequent in men as in women. 4. That operations acted as a determining cause to mental derangement where there was a previous tendency. 5. Emotional disturbance is greater at the time of surgical procedure; if predisposition to emotional disturbance, surgeons should not operate unless the necessity were urgent. 6. Mental derangement following operative procedures is more frequent than is generally supposed.

A Clinical Study of Primary Carcinomatous and Sarcomatous Neoplasms between the Layers of the Broad Ligament.—DR. JOSEPH E. JANVRIN, of New York, said that in reporting three cases of the kind he was aware that he was dealing with a condition which had seldom been reported up to the present time, excepting the cases of malignant disease of the ovaries proper. He had learned of several other cases by conversing with his medical acquaintances. The author here gave detailed histories of three cases seen by him the past three years, in which a careful pathological examination was made by Dr. W. H. Porter. The first was a myxo-sarcoma, the third an adeno-sarcoma, the sarcomatous element predominating. The second showed a carcinomatous patch within the folds of the broad ligament. In the first there was a distinct history of trauma by repeated injections of ergotine into a supposed uterine fibroid by a homœopathic physician. In one somebody had tried galvanism. The cases showed that improper treatment might act as a determining cause in giving rise to malignant change; further, that such change might take place primarily in the broad ligament.

The Present and Improving Status of Cæsarean Surgery.—DR. ROBERT P. HARRIS, of Philadelphia, the author of the paper, being absent, it was read by Dr. Parrish. The arguments advanced were based on statistics, especially those of recent date, in their bearing upon improving Cæsarean surgery. The paper also compared the results of improved Cæsarean section, or what was generally spoken of as Sanger's operation, with the Porro. Greater success now attended improved Cæsarean under like conditions. There had been greater success in Europe than in America, which could be accounted for by a knowledge of the conditions before the operation, and the management during and after. Formerly, the conditions were better in the patient's home, now in the maternity hospitals. The difference in kind of cases here and in Europe would largely account for the more successful results in Europe. From a personal observation of Cæsarean section, the author took a hopeful view, regarding the operation as one *per se* attended by moderate risk under favorable circumstances. He had seen thirteen operations, with eleven maternal recoveries. He thought the mortality could be reduced to ten per cent. To improve our statistics we should, 1, make the operation one of election; 2, perform it either before labor, or early in its progress; 3, urge antiseptic treatment of cases; 4, cease experiments; 5, use the elastic tubing of Esmarch—many preferred strong manual compression to control uterine hemorrhage; 6, evacuate the uterus without the abdomen when it contained a dead fœtus, especially if associated with septic fluid and gas; 7, wash out abdomen by pouring in distilled water at 105°, or 110° F. where blood had entered, or there was threatened collapse; 8, collar the stump; 9, antiseptic management of the stump exterior to the sewed line by isolating it, by means of prepared packing; 10, preparation for drainage where required.

DR. H. J. GARRIGUES, objected to giving the name Sanger operation, as many had performed it before Sanger wrote his book. Cæsarean section was safer than the Porro. Hospital management here being different from that in Germany, partly accounted for the difference in results. Craniotomy was safer where there was a choice, child being dead.

Drs. Fry, A. P. Dudley, H. C. Coe, R. A. Murray, Parrish, and Egbert H. Grandin, continued the discussion, the latter by letter.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at the Shoreham Hotel, Washington, D.C., September 22, 23, 24, and 25, 1891.

FIRST DAY, TUESDAY, SEPTEMBER 22D.

President's Address.—DR. GREENOUGH, of Boston, the retiring president, reviewed the work of the Association from its birth, fifteen years ago, and showed how this Association had joined with other special societies to form the Congress of American Physicians and Surgeons now in session.

Nomenclature.—DR. WHITE, of Boston, reported for the Committee on Nomenclature and Classification that hereafter, instead of the classification hitherto in vogue, arranged according to classes, the committee recommended the Association to adopt an alphabetical nomenclature. This report and recommendation were accepted. It was further voted to publish a provisional nomenclature in alphabetical order, to be modified, if necessary, at the next annual meeting.

Dermatitis Hæmostatica was the title of a paper read by DR. KLOTZ, of New York. The affection is one which, though commonly encountered, especially in public practice, finds no place in the classification of this Association as it now exists. The disease is characterized by a varicose condition of the veins of the lower extremities, obstructed circulation, inflammation, infiltration, local hemorrhage, superficial ulceration, etc. Unfavorable positions of the extremities is one of the most important causes of the venous obstruction which determines the condition. The legs in this dermatitis are often the seat of hard infiltration, pigmentation, minute hemorrhage, and lack of elasticity in the skin.

DR. BRONSON agreed with DR. PIFFARD that the name was not a very appropriate one, and the reader acknowledged the justice of the criticism, while failing to suggest a better one.

Erythema Multiforme.—DR. DUHRING, of Philadelphia, read this paper on a case of Universal Erythema Multiforme. The eruption occurred rather suddenly in a patient who had complained of rheumatic pains, nausea, etc. The eruption was at first an undoubted erythema multiforme vesiculatum. This was followed by a general desquamation as in dermatitis exfoliativa. In the writer's

experience the case was unique, and shows how the features of distinct affections may blend or follow each other in quick succession.

Dr. Fox had recently seen a case much like the one described in a patient who had been taking copaiba. He believed, however, that two such affections can follow or run into each other.

Dr. Duhring said that all drugs as etiological factors had been excluded on careful inquiry.

An Unusual Case of Sarcoma was described by Dr. Shepherd, of Montreal, which involved the skin of the left arm, producing deep ulcers and numerous dense nodules. Amputation was resorted to, but recurrence took place and the patient died of sarcoma of the stomach. Examination showed the case to be one of spindle-celled sarcoma, with tubular adenoma of the sweat-glands.

Multiple Sarcomata.—Dr. Sherwell, of Brooklyn, read the history of a case which showed marked amelioration under large doses of arsenic. These were well tolerated, and when intermitted the improvement was suspended. Four parts of Fowler's solution were added to one of Donovan's solution, and of this combination the dose was run up to thirty drops three times daily, increasing by one drop each day; the daily dose of arsenic being at times as much as one grain. Tolerance was very marked. The tumors, which were very numerous, had been subsequently removed surgically by Dr. Wheeler, of Burlington, Vt., and after an interval of comparative health the patient had succumbed to the disease.

Lympho-sarcoma.—Dr. Zeisler related a case of lympho-sarcoma in which arsenic had given excellent results. In pigment sarcoma no good results had been seen. Zoster had followed the use of the arsenic in this case.

Dr. Hyde also gave evidence of the curative effect in sarcoma.

Dr. Robinson related an instance in which as much as sixty drops of Fowler's daily had not been followed by any improvement. He looked upon sarcomatous growths as of probable parasitic origin.

Hydrargyrum Formemidatum in Syphilis.—The use of this drug by hypodermic injection was the subject of a paper by Dr. R. B. Morison, of Baltimore. This remedy was introduced by Lieberich some years ago and recommended in one per cent. neutral solution, as being free from the dangers of abscess formation. Good results are to be noticed after the fifth or sixth injection. The reader illustrated his paper with numerous clinical cases, in which he had employed the remedy with good results. One injection is given every second day, of from twenty to thirty minims or more of the solution. The method is regarded as a valuable addition to our means of treating syphilis, and in over a thousand injections abscess was not noted, though some pain is produced.

Dr. Klotz does not use the milder soluble salts any longer, finding them unnecessary, as internal treatment suffices for the milder cases. In severe syphilis the insoluble salts are employed by him in preference.

Dr. Greenough had found patients unwilling to submit to hypodermic treatment, and unless the time of treatment was much shortened, he did not see the advantage of this method over inunctions.

Dr. Morison regarded the injections as of value for those patients who would not take the inunction cure, and as a method "to fall back upon."

Lichen Scrofulosorum was the title of a paper by Dr. Grindon, of St. Louis, illustrated by a case in the person of a lady aged twenty-one, which had existed for about a year. Only one other case had been seen in St. Louis, so far as the writer knew, and it was on account of the rarity of the disease that this case was reported. The anatomical lesion was regarded as a keratosis rather than as an acne.

Dr. Robinson had seen several cases of so-called lichen scrofulosorum, and did not think they could be confounded with acne. He believed the distinctive name justifiable.

Dr. Piffard had seen but one case, and that twenty years ago, but Hebra's description was so plain that he thought there was no excuse for confounding the disease with keratosis follicularis or any other well-recognized affection.

Dr. Zeisler believed firmly that the disease does exist. In the case which he had seen there was coincident scrofulous ulceration of the glands. He looks upon the eruption as a lichen in a scrofulous subject, but not as a scrofulous lesion in itself.

Dr. Fox referred to cases in connection with acne cachecticorum, but admitted that the eruption might occur in those not distinctly scrofulous.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirteenth Annual Congress, held at the Arlington Hotel, Washington, D.C., September 22, 23, and 24, 1891.

First Day, Tuesday, September 22d.

The calling of the roll showed about twenty-five members in attendance.

The President's Address was delivered by Dr. W. C. Glasgow, of St. Louis. He alluded to the past history of the society, considering that in its honest work it had most amply justified its formation. It should always be maintained as a separate organization. Many recent graduates and poorly instructed post-graduates have gone into this specialty, deeming it necessary only to own a spray, a saw, and a cautery to pose as laryngologists. The Society should stand as a bulwark against such ignorance and empiricism. It could be maintained at the proper standard of efficiency only by a full attendance at its meetings. To neutralize indifference in the matter of attendance, a yearly infusion of new blood was necessary, and hence it was proposed to enlarge the membership. Useless members should be dropped, as the Society was never intended to be a large one. Two members had died during the year, Dr. Hosmer A. Johuson and Dr. Ethelbert Carroll Morgan, and a warm tribute was paid to their memory.

A Case of Foreign Body in the Trachea was reported by Dr. Glasgow. A colored child, eight years of age, had swallowed a toy balloon. She had severe choking, with cyanosis, aphonia, etc., but the attack passed off and respiration was perfectly quiet in the interval. These paroxysms with subsequent quiet spells recurred several times. She had no dysphagia. Exploration revealed nothing either in the larynx or trachea. She frothed at the mouth and in the paroxysms resembled an epileptic. Lower tracheotomy was performed, but a sound passed to the tracheal bifurcation revealed nothing. A cannula was worn five days. Then after a coughing spell a red mass was found at its inner opening. This proved to be the rubber portion which, in removal, was torn off from the wooden mouth piece. The latter was coughed up above the glottis and removed through the mouth. The wooden portion had probably reached down the left bronchus, as determined by a whistling râle on that side with diminished breathing during the paroxysms. The rubber lay at the bottom of the trachea, but was so soft that it was not appreciated by the sound. The paroxysms were probably caused by the cough from irritation, driving the balloon up into the grip of the cords, which after awhile relaxed and let the foreign body fall down into its original resting-place. The recovery was rapid and complete.

Thyrotomy in a Child Eighteen Months Old.—Dr. Clinton Wagner, of New York, read a paper with this title. Thyrotomy should be done for urgent dyspnœa from obstruction due to benign neoplasms or a foreign body; in malignant disease only when the operation fairly promised a thorough removal of the neoplastic material; it should never be done in tuberculosis. Dr. Wagner had

operated ten times, six for malignant disease, in which all the patients died from a recurrence, and four times in children. The age of the patient in the present case was the youngest on record. The operation was done before a positive diagnosis had been made as to the cause of dyspnœa, lasting three months, in a child who had been exposed to cold and wet. She also suffered from nightly spasms of the glottis, the least cause sufficing to bring on an attack. Tracheotomy was first performed, and then, after two weeks, thyrotomy, the postponement of the case being due to the patient's poor general condition. A small papilloma was found on the posterior part of the left cord. The child did well, and the function of the larynx was fully restored, the voice steadily returning. While the cannula was still being worn she died of the grip, eleven months after the operation. The corking up of the cannula showed that the larynx was pervious, as she breathed perfectly well.

Dr. C. C. Rice, of New York, spoke of the desirability of making a positive diagnosis previous to operating. If we lessened reflex action with a weak cocaine solution, and then gave just enough chloroform to render the patient unconscious, we might in children be able to make a thorough laryngeal examination and operate per vias naturales. In the latter event, as soon as the child began to struggle and get cyanotic, we could intubate. Then, as soon as the patient was quiet, we could remove the tube and proceed again. He had tried this alternating method with success.

Dr. E. Fletcher Ingals, of Chicago, advocated the use of the finger in diagnosing a laryngeal obstruction in the child anywhere above the cords. Drs. J. N. Mackenzie, of Baltimore, and J. C. Mulhall, of St. Louis, also discussed the paper.

The Tonsil in Health and Disease.—The paper was read by Dr. Harrison Allen, of Philadelphia. The tonsil is an association of diverticula on the side of the pharynx. On the walls of these diverticula appear follicles and mucous glands. The former are closed sacs, and not open spaces. These facts are contrary to current clinical expressions. The lingual tonsil was a simple, and the faucial a compound, structure on the above type. Crypts are produced by a depression of groups of diverticula, thus forming a central opening. The morphology is greatly disturbed by diseased action. The tonsil, as a whole, is a rounded mass with a crypt pointing downward, the whole mass being compressed more or less by the palato-glossus muscle. The whole pocket in which the tonsil lay is lined by the "involucrum of Haller." In hypertrophy it is the lower part alone which is enlarged. Higher up is a small "velar" tonsil, so called, which if enlarged is the supernumerary tonsil of some authors. The latter may be pedicled.

The functions of the tonsils are unknown. They are large in children, and in size seem to be in inverse relation to the thymus gland. They are also relatively large at the time when hæmatophoretic changes are taking place in the marrow of the long bones. Unlike the Peyer's patch, they seem to have no relation to any specific morbid process. The frequent occurrence of tonsillar diphtheria is merely due to the mechanical entangling of the contagion.

Very often pellets exist in the crypt. We should look for its mouth, slit it up and sear the edges with a cautery. In hypertrophy we have intercommunicating canals or sinuses through the tonsil. This condition is usually associated with adenoid disease of the pharynx. The latter should first be removed and the tonsillar fistula slit up. Tonsillotomy will not then be necessary. Any operation to be successful must conform to the morphology of the part operated on. This the transverse incision of tonsillotomy does not so do. After the slitting up, outlying tags of tonsillar tissue must be removed and a free use made of astringents.

Tonsillar cysts are rare. Abscesses are generally peritonsillar, but we may have a true chronic abscess containing a very little pus but keeping up a constant irritation for years and years. Incision must not be made too high up. Suppurative tonsillitis, so called, is not always peritonsillar. Incision rarely causes any hemorrhage. The internal carotid is never injured. The blood escaping comes either from an abnormally large branch to the tonsil or from an enlarged ascending pharyngeal.

Dr. Jonathan Wright, of Brooklyn, had found it preferable to remove enlarged tonsils before operating for adenoid, because he believed the growth of the latter to be caused often by the damming up of the vaso-pharyngeal secretions of the tonsil masses. When the latter were removed the former would often disappear.

Dr. J. O. Roe, of Rochester, advocated the use of the sharp scissors in opening these abscesses—after the method of Hilton. Drs. Rice and Mackenzie also discussed the paper.

Dr. Allen, in closing, called attention to the fact that enlarged tonsils became smaller under anæsthesia, and were by the lateral pressure of the tongue made to appear at their largest when the mouth was open.

The Troublesome Symptoms caused by Enlargement of the Epiglottis, and the Advisability of Reducing the Size of this Cartilage by Operative Measures.—A paper with this title was read by Dr. C. C. Rice, of New York. The enlargements due to syphilis, tuberculosis, and lupus were well known. The mechanical symptoms were tickling, a sense of fulness in the throat, empty swallowing cough, and, as a sequel, even a chronic catarrhal laryngitis. When the lingual tonsil was enlarged, or there was any cause of irritation between the epiglottis and the tongue, all these symptoms would appear. He believed also that there was a true hypertrophy of the cartilaginous elements of the epiglottis, in many instances giving rise to the same train of disturbances. The mucous membrane became congested and inflamed. The organ fluctuated in size and was always more or less congested, while the congested condition of the larynx, having been once set up, remained stationary. The epiglottis might be congenitally enlarged. It was often pendulous, due to relaxation from hot climates. Its enlargement might be due to injuries, tobacco, alcohol, gastro-intestinal disturbances, or the general congestion of visceral disease. Rarely was it œdematous.

To treat the condition, surgical interference was necessary. Astringents were useless. The galvano-cautery was followed by too much inflammatory reaction to be safe. Cocaine would relieve and perhaps cure a mild case. He followed its application with a coating of one of the oily products (albolene, etc.). Long-bladed scissors or cutting forceps seemed to promise the best results, and were better than special epiglottitomes. He had operated in two cases.

Dr. Mulhall, Drs. Vanderpoel and Jarvis, of New York, and Dr. Wagner took part in the discussion. Dr. Vanderpoel advocated the use of a sharp spoon or curette. Dr. Jarvis regarded the effect of the cautery as often merely psychical.

The Result of Treatment of the Upper Air-Passages in Producing Permanent Relief in Asthma.—A discussion on this subject was opened by Dr. F. N. Bosworth, of New York. Asthma was due to a conjunction of three factors—a neurotic habit, a morbid intra nasal condition, and some exciting atmospherical state. In treating the nose, an effort should be made to bring about the re-establishment of its normal respiratory function. Since his last paper on the subject he had seen 88 new cases. Of these 42 were cured, 32 improved, 2 unimproved, and the history of 11 was unknown. The criterion of a "cure" was the absence of recurrence for a year.

Dr. Beverley Robinson, of New York, called attention to the relation of uterine displacements, stomach derangements, fibroid pulmonary changes, malaria, kidney disease, etc., to the asthmatic paroxysm. A neuritis of many different peripheral nerves might cause it. It was a very one-sided view to regard the nose as the only seat of a ocal change standing in a causal relation to the disease.

Dr. Roe, of Rochester, regarded asthma as always due to some change in the bronchial mucous membrane. A preceding nasal abnormality is perhaps the most frequent antecedent cause, but the latter may set up many independent centres of irritation.

The discussion was continued by Drs. Wagner, Shirly, of Detroit; Mackenzie, E. Fletcher Ingals, of Chicago; Mulhall and Glasgow. The general drift of the discussion was that asthma in its causes was a Protean disease, and that to include in the necessary conditions of every case a nasal factor was entirely erroneous. What the other speakers called cardiac asthma, gastric asthma, etc., Dr. Bisnuth only considered as manifestations or causes of the neurotic state, which he mentioned as one of the three main factors of the condition.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held in the Grand Army Building, Washington, D. C., September 22, 23, 24, and 25, 1891.

First Day, Tuesday, September 22d.

President's Address.—The meeting of the Association was called to order by the President, Dr. F. S. Knight, whose address inaugurated the proceedings of the day. The deaths during the past year of Drs. Johnson, Kretchmos, Morgan, and Porrish, members of the Association, were mentioned with expressions of eulogy and regret, and a brief summary of the history and progressive advancement of the Association constituted the introductory portion of the address. The attention of the Association was called to the practical value of a careful study of our therapeutic resources in medical springs and natural waters, illustrated by the statement that one hundred million of dollars are annually spent abroad by Americans at health-resorts possessing no natural advantages over those of the United States. Much of this money could be retained in our own country by a judicious exposition of our resources in this respect. The President reiterated sentiments expressed at a former meeting, to the effect that much good might be accomplished in this direction by holding the annual meetings of the Association at different health-resorts. Physicians would thereby gain a personal and practical knowledge, and the proprietors of such resorts be stimulated to improve many faults now in existence. Conspicuous among such faults is the custom of promiscuous occupancy of the same rooms by the sick and the well, alternately. Apartments, in summer or winter resort hotels, occupied by patients afflicted with pulmonary tuberculosis should be disinfected under medical supervision. The cottage system represents the best practical solution of the question.

General versus Local Treatment of Catarrhal Inflammations of the Upper Air-tract.—Dr. Beverley Robinson read a paper with the above title. The author deprecated the tendency toward indiscriminate operative interference in cases of nasal obstruction *per se*. The nasal passages are unequal in so large a majority of individuals as to constitute almost a normal condition. If such obstruction from deviation of septum, etc., can be demonstrated to be a cause of disease, then it should be removed, of course. He did not believe, however, that nasal obstruction was so frequent a cause of disease of the nasal lining membrane or of the ears, eyes, and tonsils, as had been claimed. Warm medicated inhalations are serviceable in catarrhal inflammation of this region, but require added caution, as there is increased susceptibility upon exposure after using them. The nasal douche is often a two-edged sword, with ear trouble as a frequent sequence. A close and clear relation can often be demonstrated clinically between general constitutional state and local disease of the catarrhal type in the upper air-tracts. The author had seen many cases of nasal catarrh remain obstinately unaffected by local treatment, the condition disappearing, however, promptly upon the relief of a coincident and related gastric catarrh or torpid, inactive liver. Hypertrophy of the nasal mucous membrane often coexisted with gastric catarrh of the chronic type, which latter must be relieved before the tonsillar troubles will disappear, in many instances. Treatment by galvano-cautery often relieves, obviating the necessity for surgical removal. Cauterization is innocuous except in certain conditions of catarrhal inflammation of the nasal mucous membrane, characterized by great dryness and irritability, the formation of scabs and crusts, and a tendency to bleed easily. Carbolized vaseline, or better, Goulard's cerate freshly prepared, afforded great relief in this class of cases. He did not use as often as formerly the saturated solution of sulphate of copper, once a favorite application in such cases. The association and evident inter-relation of catarrhal affections of the upper air-tracts with the rheumatic and gouty diathesis, had been frequently observed by the writer. Such patients were not benefited by exclusively local treatment. A sojourn at some appropriate resort, with the free exhibition of alkaline and anti-rheumatic mineral spring waters would effect a cure. Enlargement of the lingual tonsil, a frequent cause of a most obstinate cough, which had been variously termed hysterical, anæmic, or nervous, often depended upon a rheumatic or lithæmic diathesis. He had seen it relieved by outbreaks of overt rheumatism. The mechanism of action involved in the production of this cough by enlargement of the lingual tonsil was through an irritation from pressure upon the epiglottis. Cautery would, at times, relieve this condition, but not always. Carbolic acid and glycerine applications are also effective in some instances. Globus hystericus is quite often due to the same cause—enlarged lingual tonsil. With regard to chronic laryngitis, he did not believe, with Bosworth, that chronic laryngitis was always a secondary condition, and due to obstruction or other nasal disease. Therefore, treatment should not necessarily be directed to the nasal cavities for the relief of chronic laryngitis.

In hay fever he considered local applications of rather more value than change of residence. A perverted condition of the peripheral nerves is responsible for many of the symptoms. Cauterization of this hypersensitive surface was often of great service. He was not prepared to express a final opinion as to the value of the ice-bag treatment, but had seen it render excellent service.

Finally, as regards the important question made necessary at times by expediency or financial considerations, "Shall the subject of catarrhal inflammations of the upper air tracts be treated by the specialists or the family physician?" be assumed the position that the best interests of the patient are subserved by a broad view of the subject, much more likely to be taken by the general than the special practitioner, a position corollary to the demonstration of an intimate relation between the local symptoms and causative constitutional states of disease.

In the discussion which followed Dr. Bosworth, of New York, said that, while he believed naso-pharyngeal affections to be often clearly related to general disease, he considered nasal disease as a purely local affection. Local treatment for chronic nasal disease such as hypertrophy, polypi, etc., by sprays or astringent applications, emollients, etc., he thought utterly useless, and that surgical interference offered the only means for a permanent cure.

Dr. Ingals, of Chicago, thought that local treatment for catarrhal inflammations which were acute or subacute would often cure, but that they were useless in chronic affections of this type. He also agreed with the author of the paper, that in many instances there was an intimate causative relation between the local disease and some general morbid state. The phenomena of so called globus hystericus he had found due to spasmodic conditions of the œsophagus as well as to enlarged lingual tonsil.

Dr. Shurley, of Detroit, deprecated surgical procedures in cases of nasal disease, unless such a degree of stenosis existed as to make positive its relation as a cause of the catarrhal inflammation. He had examined carefully two hundred cases in which there was either deviation of the septum or some other abnormal state, and yet there had resulted no annoyance to the individual.

Gymnastic Exercise as a Prophylactic and Remedy in Chest Diseases.—A practical paper bearing the above title was read by Dr. Ott, of Boston, whose opportunities for observation as medical director of a city gymnasium had convinced him that in scientifically applied gymnastic exercise, there was to be found a most valuable prophylactic agent in diseases of the chest, and a means second to no other in certainty of results, for the maintenance of a sound and vigorous condition of the heart and lungs under the trying ordeal of an indoor life. He had repeatedly observed two conditions, especially, which are suggestive of future disease, and which are greatly benefited by appropriate gymnastics. First, a certain lack of vigor and firmness in the action of the heart—"sedentary heart"—often accompanied with overweight and shortness of breath. Such subjects have probably taken little if any exercise, and have led indoor, sedentary lives for years; second, poor and incomplete expansion of the lungs with diaphragmatic breathing and disuse of the intercostals. These conditions, though not representing actual disease, are a menace to the individual, placing him just within the border line of absolute morbid states of heart or lungs, as proving inadequate to do their part when unusual demands are made upon them.

For individuals of the sedentary heart class the gymnastic exercise appropriate (based upon data afforded by careful examination) is first, light, slow work, rapid walking or slow running, chest weights, gentle rowing, and free-hand exercise. If the case is one of poor lung expansion, he is put upon lung-expanding apparatus of various kinds, rowing, free hand work, or class work with wooden dumb-bells. Swimming is one of the best forms of exercise for expanding the lungs. The spirometer, except for testing purposes, is of little value. Frequent physical examinations should be made and the exercise adjusted to varying conditions. Over-development of the chest muscles is often detrimental to good lung expansion. For the two classes described above appropriate gymnastic exercise, as indicated, will result in marked and rapid improvement, and the means here outlined may be utilized in actual disease of the lungs and heart under careful medical supervision. It is in line with the high altitude climatic method, and accomplishes much in teaching patients how to breathe properly, and in giving to the muscles of respiration the strength necessary to fulfil their function. This is especially of value in its effect upon the large class of diaphragmatic breathers, either with or without actual lung disease. The intercostals must be trained to do their share in the mechanism of respiration. The writer considers an eclectic the best system of gymnastic exercise.

Dr. Williams, of Brooklyn, in opening the discussion, expressed the opinion that proper breathing was the most important of all means of prophylaxis in phthisis. He thought it just as necessary to cultivate and exercise the diaphragmatic muscles as the intercostals in respiration. The speaker referred to some interesting observations made by him in a recent examination of Professor Checkly, the gymnast.

Dr. Gihon, of the U. S. Navy, desired to emphasize the radical importance of intelligent medical direction. He had noticed that the naval cadets who had, by reason of enthusiastic devotion to gymnastics and a high degree of training, become famous during their sojourn at the Naval Academy, had since died, many of them, of phthisis. They had either discontinued it abruptly upon leaving the Academy, or had been subsequently unrestrained by intelligent supervision. He had also observed at the Marine Barracks of the Brooklyn Navy Yard, that since the establishment there recently of a gymnasium for the men, over which there was no medical director, cases of hernia had greatly increased in number among the men.

Dr. Ingals, of Chicago, asked the writer of the paper the value of cycling as a means of exercise, especially in strengthening the muscular action of the heart. Dr. Ott considered cycling very valuable as an exercise for the heart. Riders, however, always sat with their shoulders thrown forward, and some corrective exercise should be carried out to correct a resulting defect in this respect.

The Climate of the Greater Piedmont and the Mountainous Regions of the South.—This was the title of an elaborate paper by Dr. Van Bibber, of Baltimore, in which the writer advocated the climatic and other natural advantages of the mountainous regions of West Virginia, North and South Carolina, Eastern Tennessee, Kentucky, and Northern Georgia, as affording a place of residence giving not only immunity from many diseases, but by reason of the influence upon race of physical environment, promoting the development of a high type of manhood, physically and intellectually. The races of this section, embracing about seventy-five thousand square miles, had reflected with high honor the effect of environment in forming certain mental and physical characteristics among the people, as witness the records of our nation's history. Originally the home of the Cherokee and Choctaw Indians, grain feeders, and acknowledged superior in intelligence to other tribes living in the basins and toward the coast on either side, this was subsequently the section which gave to our country such men as Thomas Jefferson, Abraham Lincoln, Jefferson Davis, Andrew Johnson, and others of like stamp. This Piedmont region furnished more men to the Union army during the late war (140,000) than did many of the Northern States. It is accessible, attractive in its resources both mineral and agricultural, picturesque in its beauty, and has an advantage over other sections of the South in the fact that the race question can never be an issue, since the climate and air are inimical to the development of the negro. As to its healthfulness, the bacillus of Koch is unknown in a certain region of Western North Carolina and Eastern Tennessee, nor have any of the bacilli of malaria been found in the same section. He did not think the Piedmont climate of so much value in curing established disease of the lungs, but as a means of prophylaxis it had no rival.

Dr. Carl Von Ruck, of Asheville, N. C., could confirm the statement that consumption and malaria did not exist in the section of country referred to, among the natives. As to the effect of the climate, altitude, and air of this region upon established disease of the lungs, he believed positively in its curative value, having witnessed such results in patients under treatment.

ASSOCIATION OF AMERICAN PHYSICIANS.

Sixth Annual Meeting, held in the Grand Army Building, Washington, D.C., September 22, 23, 24, and 25, 1891.

First Day, Tuesday, September 22d.

President's Address.—The meeting was called to order by the President, Dr. William Pepper, of Philadelphia, who then read his annual address.

Discussion on the Treatment of Visceral Tuberculosis by Koch's Method.—Dr. F. P. Kinnicut, of New York, had treated a large number of cases of tuberculosis at St. Luke's Hospital in a short time: 13 were of pulmonary tuberculosis, 7 had surgical tuberculosis, 6 lupus, 5 joint trouble, 4 intestinal trouble, 2 bone trouble, 2 tubercular prostatitis, 1 epididymitis, and 8 had rodent ulcers. At

the end of a month some grew better and went to the country. He found that preparations of tuberculin prepared fresh for every injection is much better than kept solutions, especially than the carbolic acid solution, which he does not consider good. In pulmonary tuberculosis the result of the general reaction was a guide to reinoculation. The subsidence was graded by the patient's feelings and the general condition was considered. The inoculations were usually repeated at long intervals. In one case there was two weeks' interval between the inoculations. The same line followed in joint tuberculosis and in bone tuberculosis, and after each injection the strength was gradually increased when the local reaction had subsided. Of the 13 cases of pulmonary tuberculosis there were, *A*, those with noticeable improvement in every respect; *B*, those with improvement in some respects and not in others; *C*, those that deteriorated. Of class *A*, 5 cases were from 7 to 42 years old. There was a predisposition in 3 cases; 2 were of long duration. In all there was loss of strength and cough. In none was there a history of night-sweats. There was high temperature in 4 and not so in 1 before inoculation In 4 there were physical signs and in the remainder there were no marked physical signs. The larynx was affected in one case; 3 improved in 11, 13, and 15 weeks and the worst symptoms subsided. There was a gain of weight and decrease in the amount of sputum, although at first the sputum was increased in amount; the sputum and cough were absent on discharge. There was bacilli in abundance in 4 and in 1 they could not be detected, although the clinical history undoubtedly pointed to phthisis. Prudden had counted the number. He diluted with a solution of borax in water and let stand in a jar and then counted on a cover-slip in portions of about one c.c. If there were, say 400,000 in a cubic centimetre there were about 800 on a cover-slip. In two cases the pulmonary signs almost disappeared, so improved was the case. There was no hæmoptysis. The cause of this disappearance of the signs and the improvement of the cases may have been due largely to the cod-liver oil and creasote the patients were taking, or to both, as such medication had been used before, but not, however, on improved diet and with such hopeful prospects. In class *B*, in several there were some very decided laryngeal symptoms. In class *C*, some cases, of which he gave long histories, got better at first, but after a long time got worse again, the apices softened and there were undoubted signs of a cavity.

In conclusion he thought that everyone recognized the very dangerous and ofttimes harmful action of this powerful remedy. There is a marked elective affinity of this agent for tuberculous tissue. Its value is relative and it does not cause immunity but a predisposition leads to this disease. It causes cough and general constitutional disturbances. It is not only harmful but it is not essential. It does harm by setting up the disease in distant parts of the body. These facts have been strengthened by chemical tests.

In pulmonary tuberculosis it may do good very early, but after the disease has once started it may do much harm. It is a cause of pneumonic symptoms and leads to the causation of hæmoptysis.

These remarks would not mean to show that the agent is altogether worthless. It has its uses if carefully employed, and it should have a future if used on incipient cases.

Dr. Harold C. Ernst, of Boston, thought that there was still something in tuberculin, and that we may be able to get from the pure culture of this organism a substance which when introduced under the skin will destroy the organism itself. He had treated 12 cases and 7 were not relieved. He recited at length the different prominent symptoms in each case and how each grew better or worse. He thinks there is a connection between the number of bacilli found in the sputum at each examination and the condition of the case. He showed several very excellent charts of curves, showing the condition of cases mentioned, in which some were greatly improved and others not. He repeated Koch's experiments in injecting rabbits and guinea-pigs with pure cultures of the tubercle bacillus and produced, as Koch did, the tuberculous nodules in these animals, but he could not remove them with injections of tuberculin as Koch pretends to do.

His conclusions are: 1, It has no diagnostic value and still less chemical value; 2, it did not seem to show beneficial results; 3, had had no personal experience with the ill-effects of the agent, but believed it could do much harm; 4, he would not use it again in practice; 5, it is a powerful agent and should be better understood.

Dr. William Osler, of Baltimore, had treated 28 patients in the Johns Hopkins Hospital. No case had been cured, 5 improved. In these the weight had increased from nine to fourteen pounds. In not one case did the bacilli disappear, cough improved. In 5 cases the disease was not very recent. Of 17, 9 left the hospital worse, and of those that left 1 died. None died while under treatment. He was much disappointed in the results.

Dr. J. P. Crozier Griffiths, of Philadelphia, had seen nineteen cases in the University of Pennsylvania. Of these few seemed to improve although some showed an improvement in general health, but no more than was due to the good diet and hope inspired by the treatment. In many after injections there appeared in the urine albumin and blood. The amount of reaction after injection was particularly slight. He had been much struck by this. He could not see any great use from the substance.

Dr. W. Pepper thought that tuberculin had some good in it, but it could do much harm.

The Climate of Southern California for Respiratory Diseases.—Dr. Norman Bridge read a paper on this subject. He said that many cases of both chronic and acute respiratory diseases come to this region and recover or greatly improve Many such fail of recovery, or any notable improvement, and sink and die. The proportion between these two classes it is manifestly impossible to know. Cases of long standing are less likely to improve than those in the early stage of their progress. A large proportion of those that recover (although often called consumption, or tuberculosis) are probably cases of non-tuberculous bronchial inflammation, which almost invariably, sooner or later, greatly improve or entirely recover. But cases of true pulmonary tuberculosis do recover and pass years without appreciable symptoms. The proportion of tuberculous cases recovering is small in proportion to the whole number seeking relief. It is the nearly invariable rule that tuberculous cases come here after they have lost in delay most of their hope of improving under any conditions. The vast majority of such cases leave their distant homes without an examination for bacilli ever having been made, and in those in which the bacilli are searched for and found, too often it is after months of progress of the disease have left the patient with small hope of recovery anywhere—a neglect on the part of practitioners that cannot be too much deplored. While the climate has for invalids many advantages, it has some marked disadvantages. The chief one that obtains with all dry climates is the great variation of temperature between day and night, sunshine and cloudiness. People often forget this and poorly clothe themselves and insufficiently heat their rooms, and so take colds, sometimes to their lasting injury.

The Frequency of the Localization of Phthisis Pulmonalis in the Upper Lobes.—Dr. J. West Roosevelt, of New York, reported certain work which he has done bearing upon the reasons for the frequent localization of the earliest lesion of pulmonary phthisis in the apices of the lungs. If the bacilli are carried by the air-currents we must assume the existence of some mechanical disadvantages affecting the apical parts of the lungs. It is often stated that the upper parts of the chest move less freely than the lower. This statement is, however, doubt-

ful. Certainly in women the normal type of respiration is thoracic and the upper parts of the chest move freely, while in men the lower thorax and abdomen move most. If relative chest expansion determines the seat of the lesion, the marked difference between thoracic and abdominal breathing ought to affect its localization. It does not, however, for phthisis in the female has its earliest seat in the upper lobes, just as it does in the male. The anatomical peculiarities of the pulmonary artery are such that it seems very probable that it is through this vessel that the bacilli pass and are thrown into the upper lobes, in the form of minute emboli, and that these are arrested at the places where the relatively large arteriole suddenly breaks up into capillaries in the lobules. The bacilli may enter the system through the systemic veins or the lymphatics. In the latter case they might be absorbed by any part of the lymphatic system, including the lymph-vessels of the naso-pharynx, mouth, large bronchi, and digestive tract, and enter the vena cava through the thoracic ducts. Having entered the right ventricle, they would be propelled with the blood through the pulmonary artery. In this vessel the momentum acquired by them would cause them to run along the upper walls of the main branches and to enter the branches which supply the apices.

Dr. W. H. Welch, of Baltimore, had always thought that the embolic processes were less frequently found at the apex than at the base. This would be against Dr. Roosevelt's theory. The same is true of hemorrhagic infarction. We cannot turn from experiments of animals to the human being. The bacilli probably go as easily to one part of the being as the other, but the apex is probably in the best condition to support these bacilli, *i.e.*, they grow better in the apex of the lung. They do not get there better, but having got there they grow there better.

Dr. William M. Ord, of London, agreed with Dr. Welch's argument. It seems to be due more to this selective power of the lung than to its position. The apex has a special weakness. It is prone to small inflammations and abscesses. His friend, the late Sir W. Gull, had shown the same thing in the lungs of serpents and frogs and other batrachians. It is a want of resisting power. He cannot say whether any weakness has been found at the apex or not.

Dr. A. Jacobi, of New York, suggested that if someone would spend their time in these investigations on diseased and not on healthy lung tissue, the results would be more valuable. Tuberculosis will not attack healthy lung; diphtheria will not invade healthy mucous membrane. It must be diseased first. In children some forms of tuberculosis occur most frequently at the base.

Dr. V. Vaughan agreed with what Dr. Welch said.

Dr. F. C. Shattuck, of Boston, referred to the fact that emphysema often occurred at the apex, causing a bulging there. Would this not show that the apex had plenty of opportunity to expand?

Dr. Roosevelt said his theory was plausible, but he did not introduce it as a fact, but as a theory. He doubted if emphysema was a mechanical disease, as Dr. Shattuck seemed to imply.

The Sanitary Condition of Glasgow during a Cholera Epidemic.—Dr. W. T. Gairdner, of Glasgow, Scotland, gave a short history of his position as health commissioner in Glasgow, and how, during an epidemic of typhoid fever, he prevented a serious outbreak of cholera by enlisting the interest of the churches and religious bodies of the city, and disseminating by this means a knowledge of how to keep themselves and their surroundings clean. In this way the cholera which followed in the early fall came so lightly that there were few deaths, and the people everywhere had such a good knowledge of sanitary matters that the disease could not hold. He thought that in our large cities we could use our churches and religious bodies to disseminate ideas on hygiene as well as religion.

AMERICAN ASSOCIATION OF ANDROLOGY AND SYPHILOLOGY.

Fifth Annual Meeting, held at the Shoreham Hotel, Washington, D.C., September 22, 23, 24, and 25, 1891.

First Day, Tuesday, September 22d.

Reflex Irritations and Neuroses caused by Stricture of the Urethra in the Female, by Dr. Fessenden N. Otis, of New York. The author of this paper being in Europe, it was read by his son, Dr. W. K. Otis. Stricture of the urethra in the female, the author stated, has been so rarely considered or even referred to in works on the general diseases of females, or on the special diseases of the genito-urinary organs of the female, that it might hence be inferred to be a difficulty so rare or so unimportant as to be of little practical consequence. Symptoms in the female which in the male would be at once accepted as indicating the probable presence of urethral stricture, are often referred to under the title of "irritable bladder," and attributed to causes quite independent of their possible relations to the urethra. The fact that stricture of the male urethra is accepted as usually due either to gonorrhœal inflammation or to some traumatic cause, while the "irritable bladder" in the female occurs quite independently of any previous recognized inflammation or injury, tends doubtless to prevent the consideration of stricture as a possible cause of the trouble.

In regard to the origin of organic urethral strictures, in either male or female, the author was thoroughly convinced that the foundation of at least the largest proportion consisted of cicatricial deposits due to lithiasis at periods often long antecedent to the gonorrhœa to which they are attributed. Dr. Otis then gave the histories of four cases of strictures of the urethra in the female, causing reflex troubles as varied and severe as those occasionally caused by stricture of the urethra in man. These cases were relieved by removal of the strictures. The author suggested the desirability of early exploration of the urethra by means of the urethrometer or the bulbous sound, in order promptly to eliminate at least one important element of failure in the diagnosis and treatment of such cases.

Dr. Robert W. Taylor, of New York, stated that he had seen a number of cases of stricture of the urethra in the female, some as small as No. 4 French, and two of these cases had occurred without known cause. In dividing these he had used a small grooved probe, and then cut them with a bistoury. These patients presented no symptoms excepting those common to compression of the urethra due to chancroidal or other growths at the meatus.

Further discussion of this paper was then postponed until Friday morning, when the general subject of urethral strictures will be taken up.

Genital Chancres in Women.—Dr. Robert W. Taylor, of New York, read a paper with this title. He stated that while chancres of the genital organs are very common both in men and women, extra-genital chancres occur more frequently in women than they do in men. That in women they are less regular in their course, and are often so small, benign, and ephemeral that they may never be seen or their nature not suspected. For clinical purposes genital chancres in women are classed as follows:

1. The superficial or chancrous erosion. This appears first on the mucous membrane, and is very liable to be mistaken for a ruptured herpetic vesicle, an abrasion, or a scratch. It is so benign in appearance that its nature is frequently not determined at the first examination. It begins as a red spot, somewhat deeper in color than the mucous surface on which it is seated. The secretion of this chancre is usually serous in character, or when it is irritated it may secrete true pus. Often, no evidence of induration can be felt. A striking peculiarity of the chancrous erosion is its short period of existence. It frequently comes and goes without the knowledge of its bearer, and leaves no evidence of a cicatrix.

2. The scaling papule or tubercle. This lesion is found upon the outer surface of the labia majora, upon the labia minora, upon the prepuce of the clitoris, upon the internal surface of the thighs, the inguinal folds, and the hypogastrium. It begins as a small, dull-red colored papule, which may or may not be scaly and is usually not much elevated. It becomes brownish-red or purplish-brown in color and has a sharply defined margin. It usually leaves a dark stain and when irritated it loses its epidermal covering and becomes raw and exuding. In rare cases the scaling papular chancre develops around a hair, and when this occurs it is not uncommon to see two or three or even more of these chancres. All chancres of this variety are slow in disappearing.

3. The elevated papule or tubercle—ulcus elevatum. This chancre presents the appearance of a well-circumscribed, flat or elevated lesion whose surface is similar to that of the chancrous erosion. Indeed, it may be defined as a chancrous erosion in which the hyperplastic process has been very active and productive of much infiltration. The ulcus elevatum is seen upon the mucous surface of the labia majora and minora in its most typical form. It may become much hypertrophied and around it may develop a greater or less amount of indurating œdema. It rarely shows marked induration.

4. The encrusted chancre. This is not uncommonly found upon the juxta-pudendal cutaneous surfaces, and indeed upon any portion of the integument. It has been stated that the incrusted chancres are not found within the area of the mucous membrane of the vulva, but it is not at all uncommon to find chancres in an encrusted state at the fourchette, and rarely they are found upon the clitoris and the labia minora, when these structures have come to look like integument. This incrustation forms upon an eroded surface ; it begins as a thin white film, presenting a glistening appearance, and this increases in extent and thickness until a species of false membrane is formed which is wrongly called diphtheritic membrane. Then again we find, though very rarely, the chancre called by Fournier *chancre multicolore*, or the *chancre en cocarde*, in which the surface of the chancre presents a series of concentrated zones of different colors.

5. The indurated nodule. This chancre, so common in men, is very rare in women. In men the syphilitic neoplasm or nodule as a rule circumscribes itself in compact form into a little mass ; in women this new growth tends to diffuse itself more loosely into the soft mucous tissues.

6. The diffuse exulcerated chancre. This is not infrequently observed in women of the lower order who are uncleanly in their habits and given to debauches. It presumably begins as a chancrous erosion and develops into the ulcus elevatum and from this stage further develops. The appearance of this form of chancre varies. Some times it looks raw, like beef, and at other times like an elephantine incrusted chancre.

As a rule, all chancres of the female genitals are unaccompanied with pain. Chancres of the vagina are very rare. Clerc never saw one, and Fournier says he never saw one seated beyond the vaginal ring. Bockhart reports a case of chancre of the middle portion of the vagina which had developed upon an excoriation produced by a tickler in ultra-libidinous coitus.

In reply to the question, by Dr. Palmer, whether labial chancres (of the mouth) were more common on the upper or the lower lip, Dr. Taylor stated that, in his opinion, it was largely a matter of luck. Of the labial chancres that he had seen, probably 60 per cent. had been of the lower lip.

Dr. J. Blake White, of New York, asked in what percentage of cases Dr. Taylor had observed the presence of a specific lesion high up in the vagina, notably at the cervix, where there was also a lesion in the posterior fissure of the vagina?

Dr. Taylor replied that he had observed this in two or three cases, but that he regarded it simply as a coincidence.

Observations Upon the Syphilitic Cachexia, by Dr. J. Blake White, of New York. He stated that although syphilis has been for centuries a familiar disease the essential nature of the poison is yet undiscovered. Specific diseases ordinarily exhibit a peculiar affinity for certain tissues and organs of the body, but after the initial manifestation of syphilis and its accompanying adenopathy, every structure of the body may become attacked, and if it is not checked in its inception a host of consecutive ills may ensue by which the unfortunate subject is made to suffer through life. That he can look with hope for no aid from Nature by spontaneous resolution, as occurs in so many other maladies. Certain temperaments are less prone than others to put on the cachectic livery of this disease, but experience tends rather to prove that no particular temperament enjoys an absolute immunity from it. Patients suffering from any form of scrofula or tuberculosis, or whose kidneys are diseased at the time of infection, suffer most severely from the consecutive accidents of syphilis. In such cases it becomes necessary to have recourse to remedies which not only will prove useful as direct tonics, but such also as will act through the glandular system. The eminent therapeutic value of the salts of gold in the cachexia of syphilis was strongly advanced by Christian in 1810, and Bartholow greatly extols the efficacy of the gold preparations in constitutional syphilis. The author's experience with the combined salts of gold and manganese in tuberculous and syphilitic affections has proved them especially advantageous remedies. The salts of platinum may be substituted for those of the gold. The hypodermic administration of these remedies is facilitated by their combination in fluid form and he has used glycerine as a solvent.

On the Occurrence of Nephritis in Syphilis.—Dr. John A. Fordyce, of New York, read a paper with this title, in which he stated that the occurrence of albuminuria, with and without œdema, has not infrequently been observed during the early outbreak of syphilitic manifestations. The author stated that cases had come under his observation where the albuminuria disappeared under the influence of mercury, and others in which the albuminuria had appeared coincident with the outbreak of the secondary symptoms, and to whom no mercury had been given. Reasoning by analogy, he was inclined to class this transient albuminuria with other congestive phenomena which take place in internal organs during the early period of this disease, or with the albuminuria which so frequently complicates acute infectious diseases. Aside from these cases of transient albuminuria in early syphilis, and the more severe amyloid, gummatous, and interstitial nephritis, a number of observers have noted the occurrence of an acute parenchymatous nephritis, pursuing a course not unlike the nephritis of scarlatina, terminating at times in recovery, and again passing into a chronic form. Dr. Fordyce then gave the history of a case of this kind which came under his own observation.

Hereditary Syphilitic Transmission through Two Generations, by Dr. Edmund E. King, of Toronto. This paper was a reply to certain criticisms made by M. Diday, of Lyons, of Dr. King's previous paper on this subject, read to this Association in May, 1888. In that paper Dr. King gave the history of a child in whom snuffles were first noted on the eighth day after birth, mucous patches on the twelfth day, and condylomata on the thirty-third day. The child died on the ninety-fifth day. The mother's nipples were sore and hard on the twenty-sixth day after confinement. The author could find no trace of syphilis in the father, and states that he came to the conclusion that the mother of the child had inherited the syphilitic taint from her parents ; that the syphilitic virus had, previous to the birth of the child, lain latent, having either been too weak to assert itself or the conditions for its development having been unfavorable ; that by cultivation in the fœtus it acquired virulence sufficient to cause an outbreak or re-infection through the nipple, or, second, the birth of the child and lactation

brought about circumstances favorable to the lighting up of the disease. Dr. King summarizes his conclusions as follows: First, that this is an exception to Colles's law; second, that no outside party inoculated the child; third, that the child had hereditary syphilis; fourth, that the mother was re-inoculated from it.

The three foregoing papers were discussed together.

Dr. Taylor stated that he wished to challenge a remark made by Dr. J. Blake White in his paper, to the effect that Nature does not eliminate the poison of syphilis. Dr. White had overlooked the fact that syphilis often is aborted in the first or second stages. Animals are immune to syphilis, and there may be some persons who possess the same immunity. There is sufficient clinical evidence to show that syphilis does abort itself sometimes. There are some persons in whom the syphilitic virus runs riot, while others appear able to crush out the disease. He thought Dr. White should add to those who suffer markedly from the syphilitic cachexia the tall, thin, spider-looking fellows; flabby individuals who possess a great succulence of tissue, and the light-red complexions—not the blonds, but the light-red fellows.

With reference to the paper read by Dr. Fordyce, Dr. Taylor stated that albuminuria was very common during the early stages of syphilis. Casts are rare, and if any are found they are of the hyaline character.

In reply to Dr. King's paper Dr. Taylor stated that he was sorry to see that Dr. King had again rehabilitated his case of syphilis in the third generation. He did not want to go down on record as endorsing that case.

Dr. J. Nevins Hyde, of Chicago, stated that he would like to endorse what Dr. Taylor had said about the immunity of certain persons against syphilitic infection. A number of cases had come under his observation where no symptoms had appeared after the lapse of many years.

Dr. James P. Tuttle, of New York, stated that eighteen months ago a man came under his observation with a typical papular indurated chancre. Two weeks afterward he brought his wife, who had become infected, and about six or seven weeks later he brought his mistress, who at that time had an erosive chancre. Dr. Tuttle gave these people no treatment until the secondary symptoms appeared. The man suffered from these secondary symptoms in their most virulent form, his wife developed them in a milder degree, while the mistress has never developed a single symptom up to the present day.

AMERICAN ORTHOPEDIC ASSOCIATION.

Fifth Annual Meeting, held at the Arlington Hotel, Washington, D. C., September 22, 23, 24, and 25, 1891.

First Day, Tuesday, September 22d.

Orthopedic Surgery as a Specialty.—Dr. Judson, in the President's Address, said that in a congress composed chiefly of special societies, it was proper to ask why orthopedic surgery exists and thrives as a specialty. He believed it was because orthopedic patients do not, as a rule, make absolute recoveries. There is commonly a residuum of disability and deformity, and general practitioners concur with the public in referring such cases to experts. Orthopedic patients are, as a rule, children, and in the slow methods of this specialty great disability and deformity are avoided by continuous treatment, during which the affected part increases in ability and symmetry with the growth of the child.

This is especially the domain of physical demonstration, where subjective symptoms are forgotten in view of objective signs; where diagnosis depends on what may be seen, touched, and measured; where treatment is by physical forces under direct control, and where results are recorded in degrees of a circle and fractions of an inch. Dealing thus with physical realities let us not overlook the moral verities, remembering that diligence is the price of success, and that the only desirable success is to be reached by rejecting error and cleaving to what is true.

Uniform Nomenclature in Orthopedic Surgery.—Dr. W. R. Townsend, of New York, made an earnest plea for a uniform nomenclature, and for relief from the confusion which exists in the terms used in the various hospitals in this country.

Two Cases of a Peculiar Type of Primary Crural Asymmetry.—Dr. H. L. Taylor, of New York, reported two cases. The first case, a lady, twenty-three years of age, had a difference of two inches in favor of the left side, measuring from the anterior superior spine of the ilium to the internal malleolus. Measuring from the head of the tibia the difference was one and one-eighth inch. In the other case, a girl, aged fifteen, the left leg was one inch shorter than the right. Here, also, rather more than half the shortening was below the knee.

The peculiarities of these cases consisted in the greater size and strength of the shorter limb, of which one of the patients at least was conscious, and which was plainly demonstrated in both. In neither case was there any evident lesion or impairment of the nervous, muscular, or osseous system, beyond the unequal development, and in neither case did lateral curvature exist.

On the Best Means of Preventing a Loose Joint, or Dangling Limb, after Resection at the Shoulder.—Dr. W. R. Whitehead reported a case, the main feature in the treatment of which was the use of elastic pressure, by means of a simple rubber bandage five yards long and three inches wide, applied over the dressings like the third bandage of Dessault for fractured clavicle, together with the use of an immobilization splint of Russian felt, shaped and fitted to the sides of the chest, arms, and forearm.

A Case of Spina Bifida, with Partial Motor and Sensory Paralysis, Double Equino-varus, and Purulent Bursitis.—Dr. H. Augustus Wilson, of Philadelphia, gave a very carefully prepared statistical paper on 242 cases of spina bifida. Some form of club-foot was found in 40 cases. One case was reported in detail, and the peculiar vulnerability of the soft tissues, not only of the spinal deformity, but also of the feet, and the consequent unsatisfactory results of all forms of treatment directed to remedy the clubbed feet.

Congenital Club-Foot, with Absence of Great Toe and Contiguous Bones of the Instep.—Dr. T. M. L. Chrystie, of New York, presented numerous illustrations of the patient before and after treatment. The first row of the phalanges, the first metatarsal, and the internal cuneiform bones, the two tibial and other three muscles of the leg whose tendons are attached thereto, were all absent; and the scaphoid was not fully developed. The remainder of the foot and of the child were well developed. The talipes was cured and the gait made symmetrical after six months' treatment.

A Case of Double Club-foot, Double Club-hand, and Multiple Deformities.—Dr. William E. Wirt, of Cleveland, reported the case of a child, less than a year old, having double club foot, double club-hand, rudimentary joints at knees, hips, elbows, shoulders, and wrists, with contraction of the palmar fascia. Motion at the above-named joints was possible to but a slight extent. The obstruction seemed more bony and ligamentous than muscular. There was congenital dislocation at the right hip. The mother is said to have had a severe fright during the fourth month of pregnancy. The child presented by the breech, and the labor was difficult. The child had a large head, with a depression on one side. The body was extremely emaciated. For some months the child seemed in great pain and was very irritable, and there was but slight muscular power. On a recent examination motion at the different joints was found to have somewhat increased, the child was plump, the extreme sensitiveness of the joints was nearly gone, and the mental calibre had somewhat improved. No treatment of the feet and hands had been permitted.

Deformity following Knee-joint Excision.—Dr. J. C. Schapps, of Brooklyn, reported two cases cured without fracture by use of osteoclast and brace. The result of uniting two epiphyses is a mass of soft bone, into each end of which is inserted a long lever. The vertical axis of the bones should be brought into a straight line, so that the weight is transmitted vertically, and mechanical support should be continued for at least two years after the operation.

The condition of the bone around the seat of disease is usually the cause of deformity, and this is a temporary condition after all actually diseased bone has been removed; the limb eventually becomes firm. Deformity can be permanently overcome without fracture by mechanical force. Excision is the best treatment, except in some very mild cases where faithful co-operation of surgeon, patient, and friends can be uninterruptedly continued for a number of years. The operation greatly shortens the treatment, and is the best means of abolishing the traumatism of motion which these cases can seldom tolerate. But most important, it removes the tuberculous focus, always a menace to the limb and life of the patient.

Gonorrhœal Rheumatism.—Mr. B. E. Brodhurst, of London, England, sent a communication in which he pointed out that the first attack was always preceded by a specific urethral discharge; subsequent attacks might be caused by any urethral irritation. First attacks were usually perfectly recovered from; subsequent attacks were more apt to leave more or less stiffness. Treatment consists in mercurial plasters, with compression locally and mercurial inunctions generally. Passive motions should be commenced when the painful stage has passed.

Joints left stiff after the subsidence of the inflammation should be forcibly freed under an anæsthetic, and flexor tendons cut when necessary.

The Diagnostic and Prognostic Value of High Temperature in Chronic Joint Disease.—Dr. R. W. Lovett, of Boston, sent a communication in which he said: High temperature is a constant accompaniment of acute hip disease and Pott's disease, and is to be accorded a certain diagnostic as well as prognostic value. The rise occurs independently of the presence of pus, and cases with unopened abscesses do not, as a rule, present a higher temperature than those where no abscesses are to be detached.

In a series of several hundred observations of afternoon temperature in children with hip disease and Pott's disease, it has been found that the rise is from one to four degrees, and that in a general way the rise is greater in the severer cases, and that it may be accorded a certain prognostic value in this regard; that is to say, a case of Pott's disease, for example, presenting an even temperature of 101° F., although not at the time perhaps particularly severe, must be regarded as a case likely to develop acute and severe symptoms.

Convalescent cases, and cases in the later stages which are doing well, are more likely to present normal temperatures, and the occurrence of high temperature is to be accounted a warning of trouble.

The Orthopedic Work of the Late Mr. Thomas.—Dr. A. J. Steele, of St. Louis, gave a careful review of Mr. Thomas's work, with comparison of his methods with those in common use in this country. He claimed for Dr. Physic, of Philadelphia, the honor of having used immobilization in hip disease before Thomas.

Some Lateral Traction Fixation Splints.—Dr. A. M. Phelps, of New York, discussed the question of rest and motion in the treatment of joint disease, reviewing his experiments to prove that prolonged immobilization did not tend to anchylosis, either in healthy or diseased joints. He also reported cases showing the good results and the absence of bad results of prolonged immobilization in hip disease. He then exhibited the various lateral traction hip-splints that are known by his name.

AMERICAN PHYSIOLOGICAL SOCIETY.

Fourth Annual Meeting, held at the Arlington Hotel, Washington, D. C., Tuesday, September 22, 1891.

Effects of Bleeding and Starvation upon the Proteids of the Blood.—Dr. H. Newell Martin, of Baltimore, read a paper with this title. He referred to various methods that had been tried by various authorities in separating the several albumins of the blood and the difficulties met with in making a correct estimate of the quantity of fibrinogen contained therein.

Analysis of the Blood.—After a thorough study of all the various methods tried for analyzing the blood, Dr. Martin said the one which he adopted was briefly the following: The blood is taken from the carotid artery into cylinders surrounded with ice and containing a saturated solution of magnesium sulphate. Approximately one part of the sulphate was allowed for every ten parts of blood. This is sufficient to prevent the clotting, and the corpuscles subside more readily than when larger quantities are used. Then 10 c.c. of the plasma are neutralized with an addition of one per cent. acetic acid, and finally an extra drop of acid causes a faint acid reaction. On now heating to 60° C., for five minutes, the fibrinogen comes down. It is a weighted filter, washed free from all albumins, salts, and fats, and finally heated to a constant weight at 110°. After making corrections for the volume of sulphate the result gives the fibrinogen contained in 10 c.c. of blood; 5 c.c. of the filtrate from the first precipitate are then saturated with powdered $MgSO_4$ at a temperature of 35° C., to bring down the serum globulin. This determination must be corrected for volume of added acetic acid and of $MgSO_4$ solution. Finally, all the proteids are precipitated from 5 c.c. of the salted plasma by saturation with $(NH_4)_2SO_4$. The filtrates from these precipitates were tested in every case, but no trace of albumin was ever found in them. The serum albumin can thus be determined by subtracting the serum globulin and fibrinogen from the total proteids.

Anæmia.—To ascertain the changes produced in the blood by hemorrhage, some cats were bled twice at an interval of twenty-four hours. The first bleeding varied from 55 c.c., to 81 c.c.; at the second bleeding they were bled to death. Both specimens of blood were then analyzed in the manner already described, and the results showed that the amount of proteids contained in the second bleeding was diminished, while the serum, albumin, and fibrinogen were not diminished. In observations made by some authorities it has been found that the sudden diminution of the proteids produced by bloodletting is gradually followed not only by a rise back to the normal, but even by a decided increase. A similar increase above the normal was recently found to occur in dogs by Favilli who, however, allowed an interval of several days between successive bleedings. This interval was sufficient to allow the proteids to return to and pass beyond the normal amount, while in the cats experimented upon by the speaker the interval between the first and second bleedings was never more than twenty-four hours; the second bleeding occurred before the rise in the proteids was able to reach the normal condition.

Serum Albumin and Serum Globulin.—These did not seem to follow any fixed law. Sometimes one and sometimes the other is increased by the bleeding. Why this is so cannot be satisfactorily explained.

Fibrinogen.—Hemorrhage increased the fibrinogen in every instance, the increase varying from ten to one hundred and twenty-two per cent. of its original amount. In one cat Dr. Martin determined the amount of fibrin instead of the fibrinogen and found a similar increase.

How is this Increase of Fibrinogen to be Explained?—It is well known that after venesection the red corpuscles multiply, so that in a few days the blood again contains the normal number per cubic millimetre, and it is now generally agreed that these red corpuscles are formed from special hæmatoblastic cells. Differences

of opinion exist as to the details of the process, but according to one accepted view the nucleus is bodily excluded from the hæmatoblast, the rest of the cell becoming a single red corpuscle. Howell, working in his laboratory, confirmed this view. These nuclei quickly go into solution in the lymph or blood, and the most natural supposition is that they give rise to one or more of the albumins present there.

Analysis shows that bleeding, which sets up a rapid regeneration of red blood-corpuscles, does in every case produce a marked increase of fibrinogen, and there is reason to believe that this fibrinogen does come from the dissolved nuclei of hæmatoblasts. The fibrinogen is normally present in so small a quantity that we can hardly account for its occurrence in the blood on the score of its nutritive value. But on this assumption made as to its origin, not only can its constant presence in such small quantity be explained, but also the rapid increase after hemorrhage.

The red corpuscles, like every other morphological element of the body, are all the time dying, the various pigments of the body are sufficient evidence of this. To make good this loss, a corresponding development must be going on. But by the hypothesis this means a constant supply of fibrinogen for the blood. When by hemorrhage the manufacture of corpuscles is augmented, a corresponding increase of fibrinogen is a necessary consequence.

In 1875 Alexander Schmidt and his pupil, Semmer, found that the defibrinated blood of birds, when diluted with four to six times its volume of water, or, better still, of a dilute ferment solution, would give a second clot. Such a second clot could not be produced by the serum when treated in the same way; indeed, the second clot from the corpuscles was increased when care was taken to remove the serum before the water was added. This showed that the second clot must have been obtained from the corpuscles.

Schmidt never could make this experiment succeed with mammalian blood. Now, as far as we know, the chief difference between the red corpuscles of mammalia and those of birds is a presence of a nuclei in the latter.

The nuclei of the red corpuscle of the bird can account, therefore, for the second clot, which implies that they first gave rise to fibrinogen. If the transformation of the nuclei is possible in this case, there is no reason to suppose that it would be more difficult for the extruded nuclei of the hæmatoblasts of mammals, when they are thrown into the lymph- or blood-stream.

On this theory of the origin of fibrinogen an observation made by Franz Boll also receives a plausible explanation.

He found that the blood of chick embryos, when carefully drawn so as to avoid all contamination, does not clot until the embryo reaches a certain age; that is to say, the twelfth day of incubation. Blood obtained from embryos a little older showed gradually increasing amount of fibrinogen, until, at about the sixteenth day, a regular clot is formed.

Dr. Martin said that he had already referred to the fact that destruction and regeneration of the red corpuscles go on simultaneously, but we must suppose from that that each individual corpuscle lives for some time, during which it contributes its share to the maintenance of the organism. The length of life of the corpuscle must depend on many circumstances; no determinations of its approximate length have come to my knowledge. However, I do not think it will do violence to any established facts to suppose that it may equal about ten to twelve days in embryo chicks. If this were so it would not be difficult to explain Boll's observation.

The red corpuscles of the chick being nucleated, no fibrinogen is produced during their development, and the blood cannot clot.

This solution of nuclei and the consequent appearance of fibrinogen is deferred until the corpuscles first formed begin to die and disappear; that is, the tenth or twelfth day, according to the hypothesis, and that is what Boll actually found. After that age fibrinogen begins to appear in the blood.

It would be desirable, the speaker said, to give this theory for the origin of fibrinogen a firm support on chemical grounds, but in the present state of our knowledge of the chemistry of the proteids it can hardly be hoped to trace the relationships between the constituents of the nucleus and the fibrinogen of the blood which would account for the ready transition of the former into the latter.

Respiratory Changes of Intra-thoracic Pressure.—Dr. S. J. Meltzer, of New York, followed with an elaborate paper on the "Respiratory Changes of the Intra-thoracical Pressure, Measured in the Mediastinum Posterior." He stated that at present there were three different methods of determining the intra-thoracical pressure: by tying a monometer either in the trachea of a dead animal, or connecting it directly with the pleura or with the œsophagus of a living animal. All of his attempts with these methods were unsuccessful, and he would only mention that the pressure in the œsophagus was found to be about equal in all its parts, but at the same time it was evident that the œsophagus was not the proper place to determine the intra-thoracical pressure, as it is modified by the thickness of the wall of the œsophagus and its irregular contractions. He therefore resorted to a new method, which had all the advantages and none of the disadvantages of the œsophagus—it is the mediastinum posterior. His experiments, with one single exception of a dog, were conducted on rabbits.

The animals were first narcotized with chloral, after which a catheter was introduced into the mediastinum. The animal was placed upon its back, the skin of the neck cut lengthwise on the larynx and opposite the cricothyroideal ligament, a path was bored with a blunt instrument on the left sterno-hyoideal muscle to its outer margin, and here a narrow entrance was bored behind the lower part of the pharynx. In this opening a catheter was introduced and pushed downward parallel and behind the œsophagus.

The ascertaining of the state of the pressure in the mediastinum was done by connecting the catheter either with a water monometer or with a Marcy's tambour, by means of a rubber tubing.

In his experiments on these animals he found that the main inspiratory undulations were found to appear in the mediastinum posterior, only below the fourth and fifth ribs, while above this the change of the pressure during the inspiration was either hardly measurable, or it did not amount to more than a few millimetres of water.

In conclusion, he stated that although it seemed to him that his experiment on the mediastinum made it indeed probable that the apices and the back part of the upper third of the lungs do not participate in the breathing as strongly as the other parts of the lung do, in consideration of the importance of this conclusion we should not consider it as proven until it was tested by experiments made on the pleural cavity directly or within the lungs themselves.

AMERICAN PEDIATRIC SOCIETY.

Third Annual Meeting, held at the Arlington Hotel, Washington, D. C., September 22, 23, 24, and 25, 1891.

First Day, Tuesday, September 22d.

President's Address.—The President, Dr. T. M. Rotch, of Boston, in his address made mention of the enrolment of the society with the Congress of American Physicians and Surgeons. He spoke of the need for research in the special branch of Diseases of Children. The anatomy and physiology of children should be given careful consideration as leading to the study of the diseases of adult life. The general physician should be taught that he has but a limited knowledge of the diseases of children.

The therapeutics of childhood show the vagaries of treatment. Symptoms which in children are only due to the active growth of the nervous system are treated as if indicating organic disease. We must make use of the experts in different branches of science so that we may give our time to the study of a particular department of medicine. It should be our aim to have a lasting literature of careful investigation and the narration of facts.

Prophylaxis of Complications in Scarlet Fever.—Dr. J. Lewis Smith, of New York, read a paper on "How to Prevent Complications and Sequelæ of Scarlet Fever." The author spoke of the variations of the disease in different epidemics. He wished to call attention to the complications and sequelæ which should be given preventive treatment. He advised the use of disinfectants to the fauces at an early stage of the disorder. Recent investigations have shown that bacteria are always present in the fauces and nares, and the early frequent use of disinfectants will prevent not only the local inflammation, but also the systemic infection. Among other applications he mentioned the use of solutions of peroxide of hydrogen, corrosive sublimate, and boric acid. Eclampsia in the early stages of the disease shows great irritation of the nervous system. He regarded cold externally as especially valuable because of its antipyretic effect.

The author confidently recommended aconite and phenacetin in the severe nervous symptoms which accompany high temperature and precede eclampsia. He also spoke favorably of the use of the bromides for the nervous irritability of the early stage of the disease. The rheumatism, endocarditis, and pericarditis may be made less severe and dangerous by the use of local treatment to the fauces and by antiseptic sprays. The glomeruli nephritis he regarded as due to a micro organism, though it may be induced by cold.

Dr. J. H. Fruitnight, of New York, stated that in most cases of scarlatina the nephritis occurs in mild cases, because these are the ones that are neglected.

Diagnosis of Pneumonia in Infancy and Early Childhood.—Dr. T. S. Latimer, of Baltimore, sent a paper on "The Most Diagnostic Symptoms of the Early Stage of Lobar Pneumonia and the Differential Diagnosis from such Diseases as Meningitis, Malaria, Scarlet Fever," etc., which was read by title.

Dr. F. Forchheimer, of Cincinnati, opened the discussion by giving the differential diagnosis of consolidation of the lung from effusions. It should be remembered that in childhood it takes fifty to one hundred grammes of fluid to give evidence of its presence. In the vast majority of cases of encysted pleurisy the fluid is secondary to disease of the lung. While bulging is often great in the encysted pleurisy, it is not so in the general effusion. Auscultation can be relied upon when the quantity of fluid is great. He regarded egophony as of rare presence in pleurisy. He did not advocate the introduction of the hypodermic needle to determine the presence of fluid. From a bacteriological stand-point the differential diagnosis of lobar and lobular pneumonia should be maintained.

The Diagnosis of Broncho-Pneumonia from Tuberculosis.—Dr. W. Osler, of Baltimore, read a paper on this subject. He gave some figures showing the frequency of tuberculosis in children. They should lead to careful investigation of our cases. He stated that many serous effusions are secondary. He did not believe in idiopathetic pleurisy. A long-continued afebrile course speaks against empyema. He had not seen a case of tubercular broncho-pneumonia in which the mediastinal glands had not been enlarged. The acute diseases—measles, scarlet fever, pertussis, etc.—produce the weakness of the system, which allows of the entrance of the tubercle bacilli. The protracted character of the disease, the occurrence of hectic, etc., show the tubercular process. We cannot always state what we have. Broncho-pneumonia is a process, while tuberculosis is a disease. In infants under two years of age broncho-pneumonia is rare, while the tubercular disease is common. The physical symptoms so often fail that we have to fall back on the history.

The Diagnosis of Broncho-Pneumonia from Bronchitis; also the Temperature Range in Acute Pneumonia, both Broncho and Lobar.—Dr. L. E. Holt, of New York, continued the discussion by papers on the above subjects. The cases narrated were from the New York Foundling Asylum, and most of them under three years of age. It was the rule under three years of age to get the remittent type of fever in lobar pneumonia. The younger the child the later the crisis. After the temperature passed 104.5° F. the mortality increased with each rise of temperature. The broncho-pneumonia cases that are most favorable are the ones where the temperature is about 104° F. A continuous high temperature warrants a diagnosis of pulmonary disease, but the absence of fever does not preclude pneumonia. Localized subcrepitant râles are to be looked upon as due to broncho-pneumonia. He would regard every doubtful case as one of pneumonia.

Dr. W. P. Northrup, of New York, discussed the differential diagnosis of pleuritic effusions from pneumonia.

Dr. H. Koplik, of New York, had found encysted pleurisies due to pneumonia, and had seen them make a perfect recovery. He thought that in many cases of pneumonia in which the crisis was delayed he had found pleurisy.

Dr. A. Jacobi, of New York, stated that in his experience he had found cases of broncho- and lobar-pneumonia frequently complicated, and the crisis in that way delayed. He had also observed pneumonias which had run their course in less than the usual time. He believed that the interstitial tissue is always more or less involved, and the greater the extent of involvement, the slower will be the disease.

Continuing he stated that there are some special reasons why in children it is difficult to make an early diagnosis. The absence of sputa should be considered. The cerebral symptoms cannot always be diagnosticated. The localization of the pulmonic lesion is not always positive. An examination of the axillary region will frequently decide the diagnosis.

Dr. J. Lewis Smith questioned the diagnostic points by which Dr. Holt had been able to decide on the presence of lobar pneumonia.

Dr. W. Osler, of Baltimore, had not observed so many cases of lobar pneumonia as had Dr. Holt.

Dr. S. S. Adams, of Washington, thought that climatic conditions might influence the character of the disease.

There was some general discussion as to the frequency of the two forms of pneumonia in children.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-fourth Annual Meeting, held at the Arlington Hotel, Washington, D. C., Tuesday, September 22, 1891.

Gorham Bacon, M.D., President.

Mastoid Inflammation.—The subject exciting the greatest interest, and occupying the greater share of the time of the Society, was that of inflammation of the mastoid process. Dr. H. Knapp, of New York, reported two cases on which he had operated. In the one there was otorrhœa, fatal meningitis occurred, and the autopsy proved that death had been preventable. In the other, a congestive inflammation of the interior of the mastoid with the drum head unbroken, the operation was followed by recovery.

In the first case, besides the aural there were intense cerebral symptoms, headache, nausea, giddiness, and some stupor. In the fourth week Dr. Knapp chiselled into the mastoid process to the depth of fully one-half inch, and finding no pus desisted. The patient was at

first relieved, but afterward the symptoms returned with increased intensity, and the patient died, comatose, in the eighth week. The autopsy showed diffuse purulent meningitis, a small abscess in the jugular fossa, and a collection of pus in the attic of the tympanum. The abscess in the jugular fossa was separated from the surgical opening in the mastoid by only a thin layer of healthy bone. He thought that if the opening had gone three millimetres deeper it might have saved the patient's life.

In the second case the most prominent symptom was severe, almost persistent pain in the mastoid region, radiating thence over the head and down the neck to the clavicle. The upper part of the drum-membrane was red and bulging. Six weeks of treatment failed to give relief, and the mastoid region became tender and doughy. The mastoid was opened extensively, but nothing was found but intense congestion of the bone and lining membrane of the air-cells, from which were scooped out some granulations, the spoon being made to penetrate as far as the periphery of the drum-cavity. The patient was relieved at once and gradually got well with complete restoration of hearing. This case, considered now, almost two years afterward, Dr. Knapp states, justifies an operation in congestive mastoiditis, which, without such treatment, is apt to run for many years and lead to sclerosis.

Free Opening of the Mastoid and Removal of All Diseased Tissue.—Dr. C. J. Blake, of Boston, reported twenty-three recent cases in which he had resorted to this procedure. After shaving, washing, and disinfecting the skin a free incision was made down to the bone and the soft tissues well retracted. The bone was first penetrated with a small drill, the opening then enlarged with a larger drill and the use of the chisel. The diseased and softened bone was then all removed, mainly by curetting with a sharp spoon, which enabled one to work safely from the dura mater when this had to be exposed in the process. An incision was made in the posterior portion of the tympanic membrane, and the mastoid and tympanum washed out with a weak sublimate solution. After this, drainage was secured by the free use of the probe. In two cases the wound was completely healed in a week, and in several others by the end of the second week. It was sometimes needful, particularly in cases of long standing, to use a knife to divide bands of cicatricial tissue which give before the spoon but protect portions of diseased bone. In cases in which the operation had been too long deferred there was extensive destruction of the bone, and the healing was protracted. In one of these, in which the patient had been subjected to the inadequate operation of incision down to the bone, although there was great improvement after a more radical operation, death ultimately resulted. In another case of delayed operation metastatic irido choroiditis destroyed one eye, and one lip became involved.

Dr. E. Gruening, of New York, had found the most important symptom for the diagnosis of mastoid disease was local tenderness. Other symptoms are liable to be lacking, and he would operate though it alone were present. The incision through the soft parts should be extensive and the whole of the cortex of the bone removed, as in this way diseased cavities were found that would otherwise escape detection. If all diseased bone is removed it is not necessary to disturb the tympanic cavity, and little or no after-treatment is required. In the operation he finds it needful to make free use of a small chisel and of the ordinary bone forceps or rongeur. He thought that the wound might be entirely closed immediately after the operation, but had not tried it.

Acute Suppuration of the Middle Ear.—Dr. J. M. Ray, of Louisville, reported a case in which the acute suppuration of the middle ear was attended by septic meningitis and death. The autopsy showed no involvement of the temporal bone, and that the process must have spread to the cerebral meninges through the medium of the general circulation.

Otitic Epilepsy, Trephining, and Fatal Septic Meningitis.—Dr. B. Alexander Randall, of Philadelphia, reported a case of aural suppuration with epileptiform seizures of growing frequency, where a large exostosis nearly closed the auditory canal. Exploratory trephining behind the meatus opened the antrum without finding abnormal tissue short of the denuded antrum and attic. No cholesteatoma. There was slow healing with no trouble until the fourteenth day, when pain and swelling below the mastoid occurred, followed by severe headache, and the patient grew rapidly worse and died of meningitis on the twenty-third day. The autopsy showed a purulent subarachnoid effusion of the entire convexity, with no trace of direct communication from the temporal bone, where there was denudation of the antrum and attic with erosion of the ossicles. No lesion of the cerebrum or of the labyrinth was discoverable to account for the epileptiform convulsions, and the septic infection had to be ascribed to absorption along the trephining track. A series of specimens were shown from fatal otitic cases, illustrating various channels of communication of the inflammatory process to the intracranial structures.

Use of the Leiter Coil in Mastoid Disease.—Dr. Gorham Bacon, of New York, had found this a valuable means of treating the first stages of mastoid inflammation, and had obtained with it very satisfactory results.

Excision of the Membrana Tympani and Necrotic Malleus for Chronic Purulent Otitis Media.—Dr. Charles H. Burnett, of Philadelphia, reported four cases treated in this manner. The operation was performed under ether, with the ear illuminated by an electric headlamp run by a small storage battery. All rational routine treatment was tried on these cases before resorting to this surgical procedure. In the first case the suppuration, after lasting for twenty-five years, was checked in nine months. The hearing was unaltered. In the second, which was of six years' duration, the hearing improved from ten inches to four feet in two weeks after the operation, and it is now ten feet for isolated words. The discharge has been lessened by the operation, but not checked, after the lapse of more than a year. In the third, one of very chronic suppuration of the attic space, in which the hearing was reduced to nothing and in which the patient had frequent cholesteatomatous collections in the middle ear, and pain, the operation at once checked the discharge and the hearing rose to two feet in the course of a few weeks after the operation. The improved condition of the ear has been maintained for over a year. In the fourth case, in which the discharge had lasted nearly thirty years, the hearing at once rose from six inches before the operation to two feet immediately after it. At the present time the hearing distance is eight feet and the discharge from the ear has ceased.

Healing of Old Perforations in the Tympanic Membrane.—Dr. Samuel Theobald, of Baltimore, reported some attempts to effect this that had been partially successful. It was a result to be desired, because the danger of purulent otitis was thereby lessened and the hearing might be improved. The use of disks of paper, or of various animal membranes to be placed against the drum membrane he had found unsatisfactory. His best results had been attained by the use of artificial drum-membranes of absorbent cotton, moistened by vaseline. These prevented undue dryness of the canal, and the use of a saturated solution of boric acid might be resorted to for checking any undue discharge. As a means of stimulating the formation of new tissue to close the perforation he had tried the addition of balsam of Peru to the vaseline, and found it exerted such an influence.

Unusual Dislocation of the Malleus Handle.—Dr. Theobald reported a case of this condition, probably of long standing and due to previous ear disease.

Anatomy of the Elephant's Ear.—Dr. Huntington Richards, of New York, added some further points to his previous communications on this subject, and illustrated them by the exhibition of specimens.

Owing to lack of time, a number of papers were read by title, and the Society went into executive session and re-elected the following officers :

Officers for the Ensuing Year.—*President*, Gorham Bacon, M.D., of New York ; *Vice-President*, Huntington Richards, M.D., of New York ; *Secretary and Treasurer*, J. J. B. Vermyne, M.D., of New Bedford, Mass. It was decided to hold the next meeting at the same place as that of the American Ophthalmological Society, and on the day preceding its meeting.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(Continued from p. 351.)

SECOND DAY, WEDNESDAY, SEPTEMBER 23D.

The Late Manifestations of Syphilis.—DR. PHINEAS S. CONNER, of Cincinnati, opened the discussion. In the study of this subject hospital statistics were utterly valueless, partly because only the more severe forms ordinarily seek hospital care, and partly because these patients are wanderers, and their antecedent history is unobtainable. There is no sharply defined line between the early and late lesions, but only with the end of life terminates the possibility of the development of gummata. Those syphilitic by inheritance suffer in far greater proportion from the late lesions. According to the usual conception of bone, as simply a part of the framework of the body, it seems at first glance strange that it should so often be the seat of the late development of this disease ; but closer study shows that bone is in reality a species of lymph-gland, liberally supplied with blood. But this new view only makes us wonder why the bones are not attacked at an earlier period. In all probability they are so attacked, and the fugitive pains about the head and other portions of the body are to be considered as an expression of this condition. The weight of the newly formed bone is not proportionate to its size. In the long bones it is above rather than below the epiphyseal line, and hence the comparative rarity of syphilitic joint disease. The frequent periosteal disturbances may be due not only to primary infection from the air, but to an extension through the Haversian canals to the interior of the bone. At present destructive inflammation of the bones is for the most part confined to those of the face, for the disease is not only milder, but the subjects of it are better fed and more systematically treated. The most dangerous and least understood lesions are those of the nervous system, which attacks men much more frequently than women, and is particularly common among brain-workers. Mr. Horsley has said that medicinal treatment never did more than secure a very temporary relief in cases of cerebral gummata, and that the only really effectual treatment was excision.

While recognizing the brilliant achievement and claims of modern brain surgery, the speaker thought that few would be willing to unqualifiedly endorse this statement. The motor area of the cortex is a region of very great activity, and is consequently the frequent site for the development of numerous new-growths. The convulsions produced by syphilis are often with difficulty distinguished from those of epilepsy, except by their occurring for the first time rather late in life. They are distinguished from hysterical convulsions by the absence of disturbances of sensation. In a limited number of cases psychical disturbances are prominent. They may take the form of active mania, dementia, or general paresis. Though the latter condition is very commonly associated with a history of syphilis, the syphilis is only one of a number of elements which enter into its causation. Lesions of the cord are infrequent as compared with those of the brain ; but owing to the small size of the spinal canal a mass of very moderate size is capable of causing sufficient compression to destroy the spinal cord. A large number of ataxic patients have unquestionably had syphilis at sometime or other, but tabes is not of true gummatous origin. Antisyphilitic treatment rarely cures it, and often does not even retard the progress of the disease. Locomotor ataxia can be regarded as a sequel but not as a lesion of syphilis. It bears somewhat the same relation to syphilis that post-diphtheritic paralysis bears to diphtheria.

Everywhere and at all times the development of the late manifestations of syphilis means danger to life. The author then reviewed some of the theories which had been offered in explanation of the long intervals during which syphilis lies dormant, a subject which is most perplexing.

Other diseases, by lessening the subject's powers of resistance, tend to aggravate and hasten the progress of syphilis. Occasionally, and particularly in the tongue, a gumma undergoes cancerous degeneration. In certain localities, especially in the breast, a gumma may be mistaken for a cancer, and it is quite conceivable that many reported successful operations for malignant disease can be explained in this way. In one who has had syphilis any traumatism may be the starting-point of extensive syphilitic lesions, even though there may have been a latent period of many years.

DR. ABNER POST, of Boston, continued the discussion, speaking from the stand-point of the clinician, and confining his remarks to certain points in which he was specially interested. He thought that most physicians were too slow to accept the diagnosis of syphilis in patients who had passed the period of infancy, although if they were confronted with the same lesions in an adult they would unhesitatingly pronounce them syphilitic. It was almost impossible to make any reliable estimate as to the proportion of cases in which tertiary symptoms occur. Drysdale calculated that eight per cent. showed such lesions, while other observers say between five and twenty per cent. Fournier has shown that by far the larger number of the so-called late symptoms occurred in the third year, diminishing after this, so that it might be considered as decidedly rare after ten years. Out of 2,395 "late," 1,023 appeared in the first five years, 700 in the second five years, 322 in the third period, and at the eighth period of five years there were but twelve cases. It is probable, therefore, that only about twenty per cent. show the much-dreaded late manifestations. There seems to be no method of treatment which will allow us to promise absolute immunity from subsequent attacks. Enlargement of the lymphatic glands is one of the most constant symptoms of early syphilis, but in late syphilis this is almost without diagnostic value. The majority of cases of cervical adenitis demanding operation are of a tuberculous nature ; but in rare cases, probably of syphilitic origin, the speaker said he had succeeded by antisyphilitic treatment in causing them to entirely disappear. It is of practical interest to inquire as to the trustworthiness of nocturnal bone-pains as a diagnostic sign. All clinicians will readily admit its undoubted value, but it should be viewed with suspicion when occurring in localities not commonly the seat of syphilitic periostitis. The syphilitic pains occurring in childhood are not generally recognized, and consequently lead to frequent and grave errors of diagnosis. They are often mistaken for "growing pains," or for rheumatism, and are therefore treated for a long time without success. Syphilis attacks the shafts of long bones by preference, whereas tuberculosis attacks chiefly the bones of the wrist and ankle.

It is well not to forget that the syphilitic processes which we know occur about the liver and spleen may at times give rise to peritonitis, and there was but little doubt that it occasionally involved various parts of the gastro-intestinal tract. He had had a case of very severe intestinal dyspepsia, which had proved most obstinate under treatment until a syphilitic periostitis led to the administration of the iodide, when the dyspepsia was promptly relieved. Such cases occur often enough to show that syphilis invades the intestinal tract with more or less frequency. Serious lesions of the gastro-intes-

tinal tract may also take place, as is shown by syphilitic strictures both of the œsophagus and rectum. In looking over the autopsy records of the Boston City Hospital he had found 19 cases recorded by the pathologist as syphilis, and in this number were included 1 case of ulceration of the pharynx, 2 of rectal stricture, 1 in which the gastric mucous membrane was markedly eroded, and 1 of ulceration and stricture of the large intestine. The only inference which the author desired to draw from this small number of cases was that syphilis may give rise to gastro-intestinal disease, and though rare, it was sufficiently frequent to open up a fruitful field for study. The study of syphilis is a necessity of medical progress, as the possibility of its presence renders uncertain the diagnosis of tuberculosis, cancer, and other diseases. To carry out properly the study of this most important subject demanded, in addition to ample clinical material, a hospital devoted entirely to this branch of medical science.

Dr. Robert T. Edes followed, with remarks upon syphilis of the nervous system. A careful recognition of this form is a matter of the last twenty years, during which time the literature of the subject had become very voluminous. Some recent researches of Drs. Taylor and Van Gieson are of special interest, as showing the great importance of the arterial lesions throughout the whole course of the disease. While syphilis was often associated with locomotor ataxia, this ataxia is in no sense a syphilitic disease. It is also found to be common in general paresis, even after making due allowance for errors in statistics.

Dr. J. Nevins Hyde spoke of some statistics which he had collected from 1,000 consecutive cases of syphilis occurring in private practice; 79 of these had tertiary or "late" manifestations; 11 were treated for both early and late symptoms; and 13 exhibited the so-called "late" symptoms within one year of infection. Most of these patients were between thirty and thirty-five years of age. Fournier, in the twenty-nine years of his experience in the French capital, saw 2,600 cases of tertiary syphilis in private practice, and in about thirty-two per cent. of these there was some involvement of the brain and cord. This very large proportion of cases of nervous symptoms was not to be found in this country or in many others. In considering the causes of late syphilis, he would place first on the list malnutrition, including in this class many patients who had an excess of fat. Next in importance may be classed alcoholism and the excessive use of tobacco, and lastly, he would place complete absence of treatment, or insufficient and injudicious treatment.

AMERICAN SURGICAL ASSOCIATION.

(Continued from p. 353.)

Second Day, Wednesday, September 23d.

Aseptic and Antiseptic Details in Surgery, by Dr. A. G. Gerster, of New York. Personal cleanliness and cleansing of the field of operation are to be accomplished by mechanical measures rather than by disinfectants. The dirt and oily matter of the skin is removed by emollient potash, soap, and stiff brush. This is followed by the germicidal lotion. The hands of the surgeon may be sterilized in the following manner: The nails are trimmed short, the hands scrubbed with soap and brush in hot water for one minute. The nails are then cleaned, and the hands immersed in strong alcohol and then washed in a 1 to 1,000 corrosive sublimate solution. Brushes require careful attention. They may be sterilized by boiling for five minutes in water containing one per cent. of washing soda. They should be kept in a 1 to 1,000 bichloride solution.

Instruments are sterilized by boiling for five minutes in soda solution, in a covered vessel. The addition of the soda prevents formation of rust.

Dressings are rendered absorbent and sterilized by steam. Strong antiseptic agents in dressings are objectionable from their action on the skin. Dressings may also be sterilized by boiling in soda or potash lye.

The use of Florida sponges was recommended, as owing to their cheapness they can be used once and then thrown away. Boiling of sponges is to be condemned. Sponges are best prepared by beating, followed by immersion in dilute muriatic acid. Acid is removed by washing. Then immerse in water for two days to permit the spores to germinate. Each sponge is then kneaded in hot water for one minute with potash or soft soap. They are then placed in five per cent. carbolic solution for twenty-four hours. As a substitute for the large flat sponges used in laparotomy, he recommended the substitution of pads of absorbent gauze.

In operating, few instruments, sponges, and assistants should be employed. The dissection should be clean, the tissues being cut rather than torn. Irrigation should not be employed, except when special indications present. In the abdominal cavity irrigation was condemned; when the peritoneal cavity is contaminated by pus, etc., simple wiping away of the matter is sufficient. In perfectly aseptic operations, no drainage is required. Iodoform gauze can often be substituted for the use of tubes. Drainage by tubes is required when there is progressive suppuration. In combating septic morbid processes, mechanical measures, such as incision, drainage, and irrigation are of more importance than chemical measures.

Dr. J. Collins Warren, of Boston, described the details of operative surgery as practised in the Boston City Hospital, the Massachusetts General Hospital, and the Children's Hospital.

Dr. J. William White, of Philadelphia, thought that the time had not yet arrived when the use of antiseptics could be dispensed with. He preferred an antiseptic dressing in all cases, except where the wound is absolutely sterile and where no discharge is to be expected. While in a general way he agreed as to the value of mechanical measures in cleaning the skin, he saw no good reason for throwing aside entirely the use of the weaker chemical solutions. There are so many cases in which we cannot be sure that the wound is aseptic, that antiseptic dressings become of importance. He had tried the gauze substitute for sponges in abdominal work, but had found it objectionable from the fact that when the gauze remains long in contact with the intestine, threads of the gauze adhere.

Dr. Joseph Ransohoff, of Cincinnati, said that in some cases it was absolutely impossible to render the part aseptic, and cited cases illustrating this point. In cases where it becomes clear that the wound is infected, he removes the dressings and soaks the part in hot water. He had discarded the use of sponges altogether. In the majority of cases he employs the aseptic dressing but could see no harm in the use of antiseptic dressings. Dressings, etc., in private practice may well be sterilized by heating in the oven. He thought that tight closing of the wound should be practised oftener than it now is. Drainage is rarely used except in wounds already septic. He often uses cat-gut for drainage. In the septic cases he thought that probably the surgeon was often responsible for the infection of the wound. By clean incisions, cutting far away from the disease, and by not using the sharp spoon too freely, infection of the wound in suppurating cases can often be prevented.

Dr. E. M. Moore, of Rochester, asked what objection there was to irrigation? In amputations, for instance, irrigation with a 1 to 1,000 bichloride solution affords a ready means of removing clots, etc. The clots are removed and the wound can be left in a dry state. If this irrigation does no harm, why not use it? Dr. Gerster had condemned it, but he had not given his reasons for such condemnation. In certain cases of abdominal section, especially where there was oozing of blood, the use of hot irrigation of aseptic water was of great service.

Dr. Gerster, in concluding, said that he did not con-

demn antiseptic methods. He employed both methods. In its proper place asepticism is infinitely superior to antisepticism, but the cases must be properly selected. Teachers must be careful not to go too far in advance of the rest of the profession. Those who have not learned the detail should be warned to stick to the older methods, and working up to the higher methods.

The Surgery of the Spine, by Dr. J. William White, of Philadelphia. The conditions discussed were congenital deformities, tuberculosis of the spine, neoplasms, and traumatisms. Under the first head, spina bifida is the only condition requiring consideration. In this, injection by an iodo-glycerine solution offers the greatest prospect of ultimate recovery, with the least immediate danger. In tuberculosis of the spine the indications for interference are the evacuation of pus, removal of a sequestrum, or of a focus of carious bone, and relief of the cord from pressure. There are records of 14 operations upon the bodies of vertebræ for abscess, with 8 cures, 5 cases improved, and one death, which had no relation to the operation. There have been 40 cases of operations on the spine for the relief of pressure. In 22 there was either improvement or cure. The effect of suspension in the treatment of Pott's paralysis has been so favorable, that it should occupy a prominent position.

Conclusions in regard to operative treatment of spinal tuberculosis, with symptoms of pressure on the cord, were :

1. The paralysis in Pott's disease is not as a rule due to a transverse myelitis or hopeless degeneration, and is not usually due to the pressure of the carious or displaced vertebræ; but is in the majority of cases the result of an external pachymeningitis, which results in the formation of an extra-dural connective-tissue tumor.

2. Speaking generally, a favorable prognosis is to be given, especially in children, in cases of Pott's paralysis in which the abscess, if any exists, can be evacuated; the treatment by extension and with plaster jacket can be employed, and the patient can be put under the most favorable hygienic conditions.

3. In cases in which all this has been tried unsuccessfully, or in those in which the disease is slowly but steadily progressing to an unfavorable termination; where, with more or less complete loss of motion and sensation below the level of the lesion, there are incontinence of urine and fæces, and the development of bedsores; and especially when acute symptoms threaten life, resection becomes entirely justifiable.

4. Operations having been decided upon for any or all of the above reasons, the prognosis will be favorable in direct proportion to the youth and strength of the patient, the absence of generalized tuberculosis, and the nearness of the lesions to the base of the sign.

5. When the tuberculous process affects the arches and there is paraplegia, we may sometimes operate, hoping not only to free the cord, but at the same time remove the focus of disease. This double indication may also be fulfilled in those cases where, without bony disease, there is posterior pachymeningitis or a tuberculoma occupying the canal.

6. If the lesion of the bodies of the vertebræ is in the lumbar region, at a point where these bodies are accessible, it might be possible, in certain cases, to expose the cord from the back, by removal of the laminæ, with the object not only of removing pressure, but of reaching and taking away the diseased bone and tubercular granulation.

7. In tuberculosis of the body of a vertebra and compression of the cord by anterior pachymeningitis, we can fulfil only one indication—liberate the cord from pressure. We should operate only in grave cases where acute compression, the appearance of respiratory complications, the rapid development of degenerative processes, force us to interfere; or where the course of a chronic case is steadily toward a fatal termination, although no advanced visceral tuberculous lesions are present.

In regard to neoplasms, it was said that every case of focal spinal lesion, thought to depend on a tumor and not distinctly a malignant and generalized disease, should be regarded as amenable to operative interference, no matter how marked the symptoms of pressure may be, nor how long continued.

Traumatism.—The indications and contra-indications for trephining in spinal fractures are based on the following points: 1. The nature of the vertebral lesion and the nature and extent of the medullary lesion. 2. The time which has elapsed since the traumatism. 3. The regional level of the medullary lesion.

Conclusions.—The following conclusions were presented :

1. Some objections urged against operative interference in spinal traumatisms, *i.e.*, hemorrhage, frequency of absolute destruction of the cord, pressure from inaccessible fragments of bone, etc., have been shown to be unsupported by clinical facts; others were largely due to a well-founded dread of *a*, the shock, in those cases operated on in pre-anæsthetic times and, *b*, consecutive inflammation, suppuration, and pyæmia in pre-antiseptic periods.

2. Some results of recent operative interference in properly selected cases of fractures of the spine are encouraging, and should lead to the more frequent employment of resection of the posterior arches and laminæ; *a*, in all cases in which depression of these portions, either from fracture or dislocation, is obvious; *b*, in some cases in which after fracture rapidly progressive degenerative changes manifest themselves; *c*, in all cases in which there is compression of the cauda equina from any cause, whether from anterior or posterior fracture or from cicatricial tissue; *d*, in the presence of characteristic symptoms of spinal hemorrhage, intra- or extra-medullary.

3. Operation is contra-indicated by a history of such severe crushing force as would be likely to cause disorganization of the cord. The question which will remain in doubt previous to operation will usually be that of the extent of damage done to the cord, and the possibility of its taking on a reparative action. As to this, the safest rule is that which has been formulated by Lauenstein, namely, that if after the lapse of six or ten weeks there is incontinence of urine or incontinence of fæces, and especially if there is also the development and spreading of bedsores, but little is to be hoped for from the unaided efforts of nature. If, however, these symptoms are absent, and if there be the least improvement, it will be proper for the surgeon to delay operative interference still longer.

Dr. H. H. Mudd, of St. Louis, dwelt upon the importance of remembering the liability of severe shock in these spinal operations. He reported three cases of bullet wounds of the spinal column, one of which ended fatally.

Dr. John B. Roberts, of Philadelphia, insisted that injuries and diseases of the spine of a surgical kind should be treated as we treat injuries of the cranial cavity. Cases of Pott's disease with angular curvature have been referred to, but sufficient stress has not been laid upon the fact that many of these cases with motor paralysis improve under ordinary remedies, the inflammatory exudation being absorbed. In traumatism of the spine we should explore the spine as we should explore the brain. In severe injuries with fracture spiculæ of bone are often driven down on the cord.

Dr. J. J. Putnam, of Boston, thought that the dangers of inflammation had not been sufficiently dwelt upon. Some cases of spinal injury, after one to four years, show some improvement. In such cases an operation may add to the improvement.

Dr. James McCann reported two cases of spinal injury in which operation had been performed. In one death followed. In the other there was great improvement.

The Treatment of Tuberculosis of Bones and Joints by Parenchymatous and Intra-articular Injections, by Dr. N. Senn, of Chicago. The following conclusions were presented :

1. Parenchymatous and intra-articular injections of

safe anti-bacillary substances are indicated in all subcutaneous tubercular lesions of bones and joints accessible to this treatment.

2. Of all substances so far employed in this method of treatment, iodoform has yielded the best results.

3. The curative effect of iodoform in the treatment of local tuberculosis is due to its anti bacillary effect, and its stimulating action on the healthy tissues adjacent to the tubercular product.

4. A ten per cent. emulsion in glycerine or pure olive-oil is the best form in which this remedy should be administered subcutaneously.

5. The ethereal solution should never be employed, as it is liable to cause necrosis of the tissues overlying the abscess, or iodoform intoxication.

6. Tubercular abscesses, and joints containing synovial fluid or tubercular pus, should always be washed out thoroughly with a three to five per cent. solution of boracic acid before the injection is made.

7. Injections should be made at intervals of one or two weeks, and their use persisted in until the indications point to the cessation of tubercular inflammation and the substitution for it of a satisfactory process of repair, or until the result of this treatment has shown its inefficacy, and indications present themselves of the necessity of resorting to operative interference.

8. If the treatment promises to be successful, symptoms pointing to improvement manifest themselves not later than after the second or third injection.

9. In tubercular empyema of joints and tubercular abscess, gradual diminution of the contents of the joint or abscess at each successive tapping, lessening of the solid contents of the fluid and increase of its viscidity, are the conditions which indicate unerringly that the injections are proving useful, and that in all probability a cure will result from their further use.

10. Moderate use of limb is compatible with this method of treatment, provided the disease has not resulted in deformities which would be aggravated by further use of the limb. In such cases correction of the deformity should be postponed until the primary joint affection has been cured by the injections.

11. Parenchymatous and intra articular medication with anti-bacillary material, has yielded the best results in tubercular spondylitis attended by abscess formation, and tuberculosis of the knee and wrist joints.

12. This treatment may prove successful in primary osseous tuberculosis followed by involvement of the joint, provided the osseous foci are small.

13. Extensive sequestrums of articular ends, with secondary tubercular synovitis, always necessitate resection; but preliminary treatment by iodoform injection into the affected joints constitutes a valuable preparatory treatment to the operation, and adds to the certainty of a favorable result.

14. In open tubercular affections of joints, incision, scraping, disinfection, iodoformization, iodoform gauze tampon, suturing, and subsequent injection of iodoform emulsion, is advised, and yields excellent results, and should be employed in all cases in which a more formidable operation can be avoided.

15. Balsam of Peru ranks next to iodoform in the treatment of tubercular affection of bones and joints, and if the latter remedy for any reason cannot be employed, or has failed in effecting the desired result, it should be given a fair trial, if operative treatment is not urgently indicated.

AMERICAN NEUROLOGICAL ASSOCIATION.

(Continued from page 354.)

SECOND DAY, WEDNESDAY, SEPTEMBER 23D.

The Pathology of Hysterical Anæsthesia, Illustrated by Two Cases Showing Some Unusual Phenomena.—DR. MORTON PRINCE, of Boston, read a paper on this subject. The peculiarity of these cases was that notwithstanding the presence of deep anæsthesia it could be proved that the patient felt any impression given to the hand. Pinching and pricking the skin was not perceived, but when the subjects were hypnotized they could accurately describe the tests which had been applied to the anæsthetic parts, and of which they had not been conscious. This showed that the impression was felt but not perceived. The most probable explanation was that the middle sensory centres (of Hughlings Jackson) were normal, but that in hysterical anæsthesia there is an inhibition of the highest sensory centres where the impressions are co ordinated with the other psychical states constituting consciousness.

Tumor of the Cerebellum, in which Trephining was Done for the Relief of Pressure.—This was a joint communication by DRS. KNAPP and E. H. BRADFORD, of Boston. The case occurred in a man, twenty-eight years of age. Family history was negative; had polio myelitis at seven months; well until 1889, then had right occipital headache, which increased; diplopia, dimness in vision, and double optic neuritis; then convulsive attacks; headache increased, and nausea and vomiting came on; became blind and lost sense of smell. Not benefited by iodide in large doses. Later, loss of hearing, some difficulty in swallowing and in articulation. Mental condition good. No involvement of thoracic organs. Operation performed by Dr. Bradford, who trephined right temporal region over Sylvian fissure. Pain was relieved. Hernia cerebri followed. Death occurred at the end of two months. At the autopsy tubercle was found in the left lobe of cerebellum.

Trephining and Excision of the Cortex for Jacksonian Epilepsy.—This was a joint communication by DRS. W. W. KEEN and C. K. MILLS. The patient was an adult who ten years ago was attacked with left hemiparæsthesia. Five years later this was accompanied by left hemispasm. The seizures increased in frequency, without unconsciousness. There was no paralysis. It was first thought it might be hystero-epilepsy and was treated accordingly without benefit. At last attacks became more severe, accompanied by unconsciousness. Dr. Keen trephined over motor cortex and removed the centres for the shoulder and upper arm. There were found thickening and sclerosis of bone and a small growth from the dura, which, upon microscopical examination, proved to be a sarcoma. Three days after operation there was paralysis in arm and leg, but power returned completely by the thirtieth day. No sensory symptoms supervened. During eight weeks after operation numerous attacks occurred, but they were of milder character. Eventually there was further improvement.

Porencephalus, in which Trephining was Done for the Relief of Local Symptoms; Death from Scarlet Fever; Exhibition of the Specimens.—This paper was contributed by DRS. DE FORREST WILLARD and JAMES HENDRIC LLOYD. The patient was seven years of age, and had spastic hemiplegia of cerebral origin. There was inability to walk and internal strabismus. Muscular development was good. There was no anæsthesia, no antecedent history obtainable. There were convulsions followed by enfeeblement of mental faculties and athetoid movements of right arm. The child was getting rapidly worse and was trephined by Dr. Willard. The patient developed scarlatina three days after the operation and died on the eighteenth day. At the autopsy there were no signs of meningitis but there was demonstrable porencephalus involving the Rolandic region.

DR. DANA, in opening the discussion, said that there was no question as to the validity or utility of operation in certain cases. The points that he would like to hear brought out were as to the propriety in operating in cases of Jacksonian epilepsy, tumors, for the relief of pain, and in porencephalus. He maintained conservative views on this subject, but would like to hear opinions relating to details in excision of the cortex, and as to operation for infantile cerebral hemiplegia. These cases were

often associated with epilepsy, imbecility, or idiocy. He would like to hear more as to the operation for cerebral tumor. He referred to his recent collection of the histories and specimens of twelve cases of cerebral tumors which had not been operated upon. Three could have been recognized, localized, and operated upon. Two others were well-defined sarcoma in the middle of central convolutions.

Dr. B Sachs mentioned that during the past year he had seen numerous cases bearing upon this question. The result of surgical interference in focal epilepsy he thought particularly distressing. He referred to Dr. Mills's case, and said that unfortunately, in spite of the operation, the epileptic attacks persisted. It had been shown that after removal of focus the secondary degeneration also affected the cortex. In cases of tumor, operation is more favorable, as secondary degeneration is less thoroughly established. In focal epilepsy we may render the case improved but not cured. He believed that no one could point to a single case with freedom from attacks for two years after operation. In operating upon porencephalus it would seem to be increasing the size of an existing cavity. Infantile cases should be carefully selected or the operation would fall into discredit. In porencephalus the motor symptoms are surprisingly great, while the mental symptoms are slight. Everything points to a pre-natal effect, rather than to an acquired cerebral palsy. Such cases as the latter are suitable for operation if seen at an early stage. This condition is frequently due to meningeal hemorrhage, and we should operate early. If secondary degeneration has taken place the operation is useless.

Dr. Nancrede, of Philadelphia, agreed with the previous speaker as to early operation, and cited a case in which no spasm had occurred for three years after operation for focal epilepsy of long standing. He believed that hernia cerebri after operation occurred as a result of encephalitis.

Dr. Bremer, of St. Louis, called attention to the importance of testing the muscular irritability in hemiplegic lesions by applying the faradic current to the shaven scalp. He had found the irritability greater on the affected side. He spoke of a successful case of operation for focal epilepsy, and had examined the excised portions of the cortex. There were no changes in the cellular elements, but there was abundant and excessive hemorrhage in the intervascular spaces. This should teach us the precaution to avoid too much pressure on the cortex while operating.

Seven Recent Cases of Brain Surgery.—Dr. William A. Hammond presented the history of seven cases in which he had operated for the relief of epilepsy or paralysis, and said that the cases were of somewhat different character, for not only was the seat of a real or supposed injury a factor in determining where to operate, but the symptoms, their nature and location, were even of more importance in deciding upon the situation of the disease, the consequent point on the skull with which it was in relation and the extent to which the operation should be carried.

Dr. Davis, of Philadelphia, referred to meningeal hemorrhage in the newly-born as being generally due to disease in the mother, such as chronic nephritis, thus transmitting vascular degeneration to the infant and a predisposition to hemorrhage. He believed in the propriety of early surgical interference only in marked cases, but the results were unsatisfactory where the mother suffered from constitutional disease.

Dr. Bullard, of Boston, agreed with Dr. Sachs in his views as to the selection of suitable cases for operation in young children, and said that although we cannot cure the focal epilepsy, we may alleviate many unpleasant symptoms. He referred to one of his recent cases in an adult with hemiplegia and epilepsy. The patient was trephined, and a hemorrhagic cyst evacuated. No attacks had occurred in two months. He thought it too early after operation to report the case. He believed that hernia cerebri may be due to a neglect of septic precautions.

Dr. J. J. Putnam, of Boston, said we deceive ourselves in believing because there are local spasms that there must be focal disease.

Extreme diffuse lesions may give rise to focal symptoms. He cited a case in illustration. This fact explains some of the unsuccessful results of excision. He agreed with Dr. Sachs in the view that the changes in epilepsy are diffuse, and advance independently of the bone lesion.

Dr. Knapp held the same opinion as to the gloomy outlook in cases of trephining for focal epilepsy, and referred to an unsuccessful case in illustration.

Dr. Morton Prince, of Boston, agreed with Dr. Putnam in regard to diffuse lesion causing focal symptoms. Literature did not seem to furnish histories which would enable us to discover the final results in focal epilepsy. We should operate and give the patient every possible benefit. He thought the relation of sensory to motor symptoms of importance. The sensory symptoms were most likely functional.

Dr. Keen, in closing the discussion, said he was not aware of the character of the tumor at the time of operation. Possibly its removal without excision of the cortex would have been better. He has had no case of positive and permanent cure. The operation, he thought, was warranted, owing to the probability of relief. As to the existence of secondary degeneration in these cases he has been unable to verify this by microscopical examination. Cases of defective development, such as porencephalus should not be operated on, but operation may prove beneficial in cases of microcephaly, but the patient is exposed to greater danger. In thirty-seven such cases there were nine deaths.

Dr. Mills said we had much to do in regard to the study of focal symptoms. Operation was unwarranted in porencephalus. He suggested direct medication of the cortex in certain cases instead of excision.

Tumor of the Mesencephalon with Exhibition of the Brain.—Dr. Lloyd read a paper with the above title, reported the history of the case, and exhibited the specimen.

Tubercular Infection of the Central Nervous System.—Dr. B. Sachs read a paper with this title. In the two cases serving as a basis for the paper, the patients had been received into the "Montefiore Home" for a non-tubercular disease of the central nervous system. In the one case, a large hemorrhagic cyst in the cortex was the residue of the process, giving rise to an infantile spastic hemiplegia in the vicinity of this cyst. Soon after admission to the "Home," where there were many patients with phthisis, a solitary tubercle of enormous size was developed, which led to a rapidly fatal termination.

In the second case, a tubercular infection hastened the course of an old chronic myelitis. The history of this case is about as follows:

J. R——, a Russian, aged sixty; family history entirely negative; well until two years and a half ago; then, after an exposure to cold, noticed a weakness of both legs; greater in the left than the right; this paresis gradually increased, associated with slight vesical symptoms. No change in symptoms for some months; then quite suddenly, about five months after his exposure to the phthisical contagion, he became absolutely paraplegic, and the reflexes of the lower extremities increased; bladder symptoms and bedsores are developed, the paralysis extends upward, first to the right arm and then to the left; anæsthesia as far as navel from below upward, and gradually extending to the lower margin of the second rib; patient has high fever, becomes rapidly emaciated, and dies about three weeks after onset of the absolute paraplegia.

Post-mortem examination: Entire absence of brain lesions, no tubercular meningitis anywhere; but the most widespread destruction of the cord from the second to the

twelfth dorsal segments, with ascending and descending degenerations. In the mass of destroyed tissues the tubercle bacilli were found in large numbers.

Dr. Sachs insists on the fact that the preceding disease of the cord furnished an excellent soil for the growth of the bacilli, and instead of growing in the lung tissues, or even in the meninges, they have grown upon the diseased substance of the cord itself. It is proper, therefore, to speak of a tubercular invasion.

Dr. Hughes referred to the unusually rapid termination of these cases with tubercular infection.

Lead-poisoning, with Special Reference to the Spinal Cord and to Peripheral Nerve-Lesions.—Dr. E. D. Fisher reported a case of chronic lead-poisoning in a man aged thirty-four. The microscopical findings showed peripheral nerve-degeneration, and sclerotic changes in Goll's columns, in the antero-lateral tract, in the region of the posterior spinal nerve-roots, as well as degeneration in the anterior cornua. He was of the opinion that lead, and probably also arsenic, affect independently the peripheral and central nervous system.

Dr. Dana had seen the specimens, but was unwilling to say the lesions were due to lead. Lead seems to possess a selective action for the peripheral nerves. He thought the changes more marked in the nerves than in the cord.

Dr. Riggs, of St. Paul, believed with Dr. Dana that lead usually affected the peripheral nerves, but in this case he thought the lesion was more likely due to arterial sclerosis.

Dr. Lloyd then showed microscopic sections from a case of lead-poisoning that had developed locomotor ataxy.

Dr. Dana presented, in behalf of Dr. Joseph Collins, two new methods of Weigert for staining specimens.

A Neuro-topographical Bust was exhibited by Dr. William C. Krauss, of Buffalo. The author defines a neuro-topographical bust as one showing the topography of the nervous system of the head and neck. Such a one might be of service to the neurologist as a means of reference and comparison, and to the surgeon as a guide in the location of the cortical centres of the brain. The bust is modelled in plaster, life size, and offers the following special features: The fissures of the brain are represented by grooved lines which are deep or shallow according to the size of the respective fissures in the human brain. In order to make them more visible they have been traced in black. The lines cannot represent accurately the intricate windings of the several fissures, but give a general outline, and thus show the relation which they bear to one another and to the cranium. The face and neck represent the various electro-motor points of the muscles and nerves. The motor points of the trunk and several branches of the trigeminus, the hypoglossal, accessorius, etc., are indicated by circles—which, to render them more apparent, have been painted yellow. The course of the brachial plexus and phrenic nerves in the neck are marked by slightly grooved lines also painted yellow. In contrast to the nerves, the motor points of the muscles are represented by smaller circles which have been painted red. The various points may be designated by small printed slips or by figures and a reference table.

AMERICAN GYNECOLOGICAL SOCIETY.

(Continued from p. 356.)

Second Day, Wednesday, September 23d.

A Unique Case of Multiple Neuro-lipomata following Laparotomy.—Dr. H. Marion Sims, of New York, reported in this paper the following unique case: A strong healthy girl, never sick, married at the age of eighteen, in 1884, and afterward suffered from vaginismus, which Dr. Sims cured by excision of the hymen. Two months afterward she began to suffer from severe pain in the region of the ovary and had epileptiform convulsions. A cystic ovary was felt, and as the patient was pregnant he thought the symptoms might be due to pressure of the gravid uterus upon the sensitive tumor. She was allowed to go to term, but even then the pain, etc., continued, and laparotomy was performed. Both tubes and ovaries had undergone change, and therefore were removed. He was sent for again in the summer of 1885, when he found her suffering extreme pain in the thick walls of the abdomen near the umbilicus. He was able to feel two or three round bodies, like shot, beneath the skin, the removal of which was followed by complete relief in a short time, when others made their appearance in the near neighborhood. They were excised as they continued to develop, and finally the entire abdominal walls were scarred by the repeated operations. A few, in the course of the four or five years during which these growths developed, appeared in the skin of one arm and on one thigh. They were found to be little nerve-nodules in adipose tissue, connected by a small nerve with the nerve system. Many physicians, including specialists, saw the patient in consultation, none of whom had seen the like before. The last nodule was removed over a year ago, since which time the patient had been well. Nothing but excision gave relief, even morphia failing to allay the pain.

The President's Address.—Dr. A. Reeves Jackson, in the first part of his Address, referred in terms of sorrow to the loss by death of members during the year. The last original member whom they had to mourn was the lovable and beloved Dr. Fordyce Barker, who had in the spring passed away from his labors full of years and honor. Other members recently lost were Drs. David H. Storey, an honorary member from Boston, and George H. Lyman, of Boston, one of the founders.

Changes Undergone by Gynecology since the Foundation of the Society.—The body of the Address recited some of the changes undergone by gynecological science since the foundation of the Society in 1876. It showed the errors which had been committed by enthusiasts in carrying to extreme operative procedures as they came into fashion from year to year during that period. A considerable amount of the reproach was connected with extirpation of the uterine appendages. It was worse than a crime to perform a serious, mutilating, and dangerous operation which could be avoided by simpler treatment. There was too common examination of the pelvic organs of unmarried girls and women. What might we expect from this conduct upon the *morale* of girls just entering upon womanhood.

The progress of medical science was impeded by immature announcements of results. Papers admitted to the volume of "Transactions of the Society" especially should undergo close scrutiny as to their scientific value. The Address pictured a high scientific and moral ideal for the members to strive for.

Cancer of the Cervix Uteri—Results in its Treatment by High Operation.—Dr. William H. Baker, of Boston, read the paper. Reference was made to the difficulty of tracing the after-history of cases treated, yet he had been able by great labor to trace all those cases which he first reported in 1882. Cases failed so often to come in time for anything like a radical operation because the early symptoms of uterine cancer were not marked, and the patient was likely to attribute any flow to the change at the menopause; and also because of the ignorance of the practitioner in failing to appreciate the condition present, or in lacking in faith in the efficiency of an operation. Eight of the ten cases operated upon by high amputation, first reported in 1882, were then well. In a second report on these cases, 1886, six cases were yet alive. Thus sixty per cent. of the cases were alive four years after the operation, and fifty per cent. were still alive, ten to twelve years after the original operation. A second series included cases operated upon between 1882 and 1889. Of this number—sixteen—in none did death

take place primarily from the operation. In ten there had been no return of the disease. One was well after eight years, two after seven, three after six, three after three, one after two years. Thus there had been no return of the disease in 62.5 per cent. of the cases. Where there had been recurrence, in one it was after six years, in one after two and a half years, in one two years, in one one year, in one in eight, and in another in five years. The points in favor of the operation, as opposed to hysterectomy, were greater safety to the patient and longer respite from recurrence. Thorough removal should be practised, following the scissors and scalpel with the cautery. High amputation should be practised in all cases of cancer of the cervix which had not become fixed by extension of the disease.

Dr. John Byrne explained his method of operating alone by the cautery.

Dr. Reamy made an eloquent appeal for the high-amputation method in the cases described.

Drs. Janvrin, W. Gill Wylie, and T. A. Emmet also discussed the paper, defending vaginal hysterectomy, although not opposing high amputation in some cases.

The Best Posture in the Different Stages of Normal Labor.—Dr. H. J. Garrigues, of New York, read an abstract of a paper on this subject. A change, he said, had taken place in the customary position in which women were delivered in the United States. Now some spoke of an American (dorsal) position, as opposed to English (left lateral), while, until thirty years ago, nearly all American obstetric writers recommended the English position. In deciding the posture which a woman should occupy during labor, we must take into consideration her comfort and safety, the child's safety, and the accoucheur's comfort, which again contributed to the mother's safety. While the child is passing through the bony part of the parturient tract the semi-recumbent position is best. The contraction of voluntary muscles and gravity co-operate with the contraction of the womb; the entrance of the head into the superior strait is favored; the stethoscope can easily be applied to the abdomen; manual pressure may be exercised on the womb. Sometimes a change of position is useful. When the vulva begins to open, the patient should be turned on her left side, and lie horizontally, her thighs at right angles with the trunk and the legs, and the lumbar region stretched. All support should be taken away from the hands and feet, and chloroform should be given. In this position the os coccyx has free scope to recede, the genitals become visible and easily accessible, while the rest of the body remains covered. The fundus uteri sinks down so that gravitation works in a direction opposite that of uterine contraction. These facts and others showed that the left lateral position offered a safeguard to the perineum. During and after expulsion of the placenta, the woman should be on her back, a position favoring Credé's method. The kneeling, squatting posture is fatiguing, predisposes to hemorrhage, makes the use of the stethoscope difficult, nearly precludes any kind of protection of the perineum, and renders the use of chloroform impossible. In cases of lingering labor it may be tried like other positions.

The Influence of Imperfect Development as a Cause of Uterine Disease.—Dr. W. Gill Wylie, of New York, said his paper was merely an elaboration of some observations presented in one which he had published nearly ten years ago. The author believed that the customs of our civilization tended to develop the brains of girls at a time when their physical energy should go to the development of the generative organs. The resulting imperfect development of the uterus rendered that organ susceptible to disease, such as catarrhal endometritis, and when afterward it should be called upon to perform important functions one was likely to find sterility or rupture of the cervix because of previous disease, etc. Reference was made to the greater prevalence of uterine troubles in the higher states of civilization; in support of this view the argument being reinforced by comparison with the animal kingdom. More out-of-door exercise, less urging at school, less mental excitement by contact with adults, was recommended by way of prevention. In treating diseases after they had arisen, the part acted by imperfect development of the uterus should be borne in mind.

The Technique of Vaginal Fixation of the Stump in Abdominal Hysterectomy.—Dr. Henry T. Byford, of Chicago, read the paper. Encouraged by the success obtained in the treatment of the stump in abdominal hysterectomy by vaginal fixation (nineteen cases with one death), I have thought it proper to again present the subject. All new methods suffer from the want of experience of the operators. During the past year I have added a little to my experience with it, and desire that anyone wishing to try it should have the advantage.

With regard to the first three steps, as given in last year's communication, viz., ligating the broad ligaments, separating the bladder from the uterus, and placing the elastic ligature, guarded by pedicle pins, I have nothing to add except that I begin separating the peritoneum an inch above the attachment of the bladder. As to ligating the stumps in three parts, I sometimes do this and sometimes only ligate the outer thirds or quarters which contain the large vessels, and place the sutures on the pared edges deep enough to act as efficient hæmostatic agents. The latter procedure is sometimes an easier and quicker one in stumps that are dense and not unusually vascular in structure. The ends of the ligatures are all left about four inches long, as before described. I have not yet seen fit to neglect an efficient ligaturing of the stump, so as to depend entirely on the clamp.

The elastic ligature is removed and the vagina perforated by hæmostatic forceps pushed down between the thumb and cervix, as the stump is held in the palm of the left hand—a very easy manœuvre. I enlarge the vaginal rent by two short scissor-snips laterally, two short ones diagonally, and a longer one forward in the median line under the slightly separated bladder. The longitudinal median cut bleeds less than a lateral one of equal length. The vaginal walls are held well up by forceps, so that there need be no danger of wounding the bladder, nor of losing sight of any large vaginal artery that might possibly be severed.

The stump is then turned into the vagina and the long ends of the ligatures given to an assistant, who draws them out of the vulva and holds them.

Instead now of putting on the clamps, I leave that as the last step, as was suggested to me by Dr. Merriman, of Chicago. The advantage of this is twofold; the peritoneal cavity is closed before I soil my hands by the vaginal manipulation, and the sewing of the peritoneum over the stump can be done nearer the surface than if it were held down rigidly by the clamps.

I then put the fingers of my left hand in the cul-de-sac of Douglas, and lift the cervix as high up toward the surface as possible, and sew the peritoneum from the bladder to the posterior wall of the cervix. As this may become a very difficult procedure in fleshy patients, I will give the steps in detail: I grasp, with needle forceps, a short, straight needle, armed with fine catgut, pierce through the bladder and peritoneum near the left stump, then through the peritoneum on the posterior surface of the cervix, and direct my assistant to tie a knot, which brings the bladder and peritoneum back over the stump; this while I am keeping my left hand in place under the stump, holding the intestines out of the way. Then I pierce the bladder-peritoneum and cervical-peritoneum again with my needle and place an uninterrupted suture across to the other pedicle. The catgut is drawn tight and the two ends tied before I remove my left hand and liberate the intestines. It is surprising what a small wound is left. In case the pelvis be deep I have the foot of the table raised for better light, and to help keep the abdominal contents out of the way. The matter of keeping the operator's left hand steadily in place during the

suturing is important, as the hand of an assistant is more in the way in a deep pelvis, and must manipulate the intestines more to keep them out of the field. If there remain any oozing, an extra catgut suture is passed so as to check it. The peritoneal cavity can now usually be closed without drainage.

The patient is then placed in the lithotomy position, the vagina opened by retractors, the clamp slipped over the stump, oozing from the anterior wall of the cervix checked by diluted Monsel's solution, and the vagina loosely packed with iodoform gauze, to be left for three days. At the end of the fourth day the vagina is gently irrigated with plain warm water, and after that twice a day with a one per cent. carbolic solution.

Suggestions of Certain Rules to be followed in Efforts to Prevent Mural Abscesses, Abdominal Sinuses, and Ventral Hernia after Laparotomy.—Dr. H. T. Hanks, of New York, read the paper. In trying to avoid mural abscess, which made hernia more liable, make a clean cut wound, not lacerating, separate the layers carefully, do not retract the lips with too much force or too long pressure, do not use too hot water, or too strong a germicide on the lip, have the abdomen aseptic by keeping on a germicide dressing a few hours before the operation. Do an aseptic operation. Change the sterilized dressing every second day. Before cutting the sutures have the patient wear a moist bichloride dressing, two or more hours, and be sure no sepsis is drawn into suture tract. Make no unnecessary punctures with needles. Do not strangulate the wound with too tight tying of deeper sutures. Sinuses are as often due to the drainage-tube as to ventral hernia after laparotomy; he believed it was much more common than generally supposed. To prevent it, he strongly urged uniting homologous tissues in closing the laparotomy wound.

Some Clinical Testimony as to Ultimate Results of Removal of the Uterine Appendages.—Dr. Thaddeus A. Reamy, of Cincinnati, read a paper with this title. Cases of malignant disease and ovarian tumors were excluded. The operations were performed from 1885 to 1889. They were 164 in number, in 144 both ovaries and tubes being removed. His conclusions were: 1. Pyosalpinx does not exist in nearly as large a proportion of pelvic disease encountered in patients among the middle and upper classes as is generally taught. 2. In cases from this class gonorrhœa does not play so important a rôle in the causation of the disease as is generally believed. 3. In properly selected cases, where otherwise incurable disease of the appendages exists, the results from surgery are not only satisfactory, but are brilliant. 4. In properly selected cases removal of the uterine appendages is more promising of relief of hystero-epilepsy than is generally conceded. 5. The practice should not be continued in the treatment of purely neurotic cases. 6. Many cases of manifest pelvic disease, including disease of the ovaries and tubes which are cured by removal, could be as thoroughly, as promptly, and more satisfactorily cured by more conservative methods without the sacrifice of these important organs. 7. Many cases reported by operators as cured are found after a few years to be no better off than before the operation. 8. Arrest of the menopause after removal of the ovaries, which took place in so large a number of the cases, tends to confirm the belief that the ovaries bear an important relation to this function. 9. The influence of removal of the appendages upon the sexual appetite has not heretofore been correctly stated (in many cases the sexual appetite was lost or much diminished). 10. The relation of this influence to the psychoses which had so often followed the otherwise satisfactory results of this operative procedure is worthy of serious consideration.

Indications for Laparotomy in the Treatment of Puerperal Fevers.—Dr. R. B. Maury, of Memphis, reviewed this subject in a general way, and related some cases which he had operated upon for laparotomy. There were three classes of cases: Those in which there was recognizable pelvic collection of septic matter, limited; those in which there was general diffuse septic peritonitis; and those in which pre-existing tubal or other abscess had burst during labor. In the first and last classes the indications were to operate. In the diffuse form he had operated twice, in both rather late; one patient survived the operation two months, and then died of exhaustion. But it was not always easy to make an early diagnosis, while the success of an operation depended much upon the date at which it was undertaken.

A Study Relative to the Function of the Reproductive Organs in American Indian Women.—Dr. Andrew F. Currier, of New York, expressed his thanks and obligations to the Indian Department in helping him get the reliable information contained in this paper. Regarding puberty among Indian girls, it took place about the same time as in whites in like climates. Some peculiar customs were gone through with when the girl began to menstruate. The menopause came on usually from forty to fifty years of age. Husband and wife left one another among some tribes, as they felt like it. The women do the drudgery. Childbirth takes place in the squatting posture, often without the presence of even a midwife. Conjugal fidelity is not marked. Both local and constitutional venereal disease is common, which would far explain the large infantile mortality. There is little disease of the pelvic organs, except among the civilized tribes. Abortion is brought on by a stick introduced into the vagina or by force applied over the abdomen.

AMERICAN DERMATOLOGICAL ASSOCIATION.

(Continued from p. 357.)

Second Day, Wednesday, September 23d.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Bronson, of New York; *Vice-President*, Dr. Shepherd, of Montreal; *Secretary and Treasurer*, Dr. Jackson, of New York. Drs. Elliot and Heitzman were elected members of the Association.

The location for the next meeting was voted to be at Casco Bay, Me., and the date set for the Tuesday nearest the 10th day of September.

Tuberculosis of the Skin.—Dr. White, of Boston, opened a discussion on the "Clinical and Etiological Relations of Cutaneous Tuberculosis." After a consideration of lupus vulgaris, tuberculosis verrucosa cutis and verruca necrogenica were taken up. The shallow ulcerations about the natural orifices of the body in patients with advanced phthisis, and due to local inoculation, were not considered of sufficient importance to warrant a separate class. Tuberculous eczema, a term used to denote an eczematous condition surrounding tuberculosis, is as objectionable as that of syphilitic eczema and should be dropped. There are undoubtedly forms of cutaneous tuberculosis about which we know but little at present, and many obscure conditions are only made clear by concomitant gland, bone, or other lesion which point to the proper diagnosis.

There is little remaining doubt that the bacillus is the direct exciting cause of all tuberculous affections. This is due to the universal presence of tubercle bacilli in all the clinical forms, including scrofuloderma. That the bacillus is always the same and identical with the bacillus of tuberculosis pulmonalis, is proven by inoculation experiments. The cutaneous forms of scrofuloderma when inoculated in Guinea-pigs produce tuberculosis; so do the bacilli of lupus, but only after a longer interval. Thus Leloir has been led to express the opinion that it is the quantity and not the quality of the bacillus which determines the effect produced. Syphilis and lepra are quite as difficult to reproduce by inoculation, but none the less their bacillary nature is quite generally believed, and the proof will probably soon be forthcoming.

Auto-inoculation is another proof of the transference

of the bacillus from one host to another. Many clinical cases show that cutaneous lupus or tuberculosis occur after the evacuation of matter from glandular and bone lesions near the surface opening. Lupus also often occurs on the seat of wounds. Transference from one person to another does not always produce the same form of lesion in the second individual, and the low vitality of the bacillus accounts for the rarity with which this transfer takes place. Numerous reports show how cutaneous tuberculous ulceration can result from ritual circumcision. The saliva of phthisical patients has frequently been seen to cause tuberculosis of the skin. Cutaneous tuberculosis of the hands is not infrequently found upon the hands of nurses and those who care for consumptives, washerwomen who handle the handkerchiefs covered with sputa, etc. Many clinical cases are cited in confirmation and illustration of this transfer to the cutaneous surface. The days of diatheses are numbered, and scientific experimentation will take the place of this explanation. Why should we not accept inoculation as an explanation for tuberculosis when we do not hesitate to do so for syphilis? Another proof is the association of pulmonary tuberculosis and cutaneous tuberculosis in the same individual. In Besnier's statistics twenty-one per cent. of lupus cases died of phthisis. Others have found much the same proportion. The writer cites three of his own cases where lupus was associated with tuberculosis of the lungs. The development of internal tuberculosis after cutaneous lesions are explained by direct transfer of the bacillus from open wounds. Some cases have been reported where, after scarification of lupus, such general phenomena have been noted as occur after inoculations with tuberculin.

The essential identity of all forms of cutaneous tuberculosis is believed by the writer to be proven by the mass of evidence presented. We cannot deny intra-uterine infection, but is it longer necessary to accept heredity? From the evidence collected within the past few years are we not justified in looking upon all forms of cutaneous tuberculosis as different phases of the same affection, and would it not simplify matters to drop the terms lupus and scrofuloderma? The sooner it is made apparent to the public that all tuberculosis is susceptible of transfer and dangerous to the well, the sooner we will be in a position to successfully combat it.

The Pathology of Tuberculosis of the Skin.—This branch of the question was discussed by Dr. Brown, of Boston. The tubercle, which is the product of the bacillus, is a nodule of so-called granulation tissue, composed of small round cells, together with larger cells, possessing a clear nucleus and large cellular elements with peripherally arranged nuclei and homogeneous centre, the Langhaus giant-cells. Cheesy degeneration is a term which should be restricted to the macroscopical appearance, and be dropped from the nomenclature of microscopy, as it is found in other conditions. Giant-cells are in the same way found in syphilis and other conditions, though a certain amount of diagnostic value must still be allowed to it. The doctrine of to-day reads, "every neoplasm that contains the bacillus of tuberculosis is tubercle, and in every tubercle the bacillus must be present, however sparingly." The first signs of new tubercle are epitheloid cells, which are seen to be produced from the fixed tissue cells by karyokinesis and not from the leucocytes or small round cells. Caution must be observed in assertions that they are produced from the fixed cells alone. There is no suppuration in tubercle, strictly speaking, and no pus-cells are found. A real suppuration is only present when tuberculosis is complicated with a septic process.

Miliary tuberculosis of the skin represents almost exactly the tubercle of internal organs. Clinically, it consists in painful ulcers situated at the juncture of mucous membranes in patients with tuberculosis of internal organs. It is also met with on mucous membranes alone. Miliary tubercle in the form of yellowish-white transparent nodules, can usually be seen. Such ulcers are rare. Here the cutis is found to be filled to a considerable depth with small round cells with occasional epitheloid and giant-cells of Langhaus. In the case examined by the reader, tubercle bacilli were present in large numbers. The differences between this form and lupus are those which distinguish an acute from a more slowly progressing tuberculosis.

Scleroderma.—Here the subcutaneous tissue and lower portion of the corium are the seat of the morbid process, which often starts from a lymph-gland. The anatomical character differs in no essential manner from tuberculosis of internal organs. The degenerative changes which subsequently take place are usually found further advanced than is the case in lupus. Specific tubercle bacilli are always present.

Lupus.—Here the starting-point is in the corium, progressing upward by extension of foci of disease. Non-specific alterations of the epithelial elements are secondarily produced, as a rule. From a purely anatomical standpoint lupus cannot be separated from tuberculosis. The rôle of the leucocytes in lupus has been greatly exaggerated and the fixed tissue-cells are, at least in the main, the parents of the epithelioid and giant-cell formations. The recent views of Unna and others were discussed at some length.

Tuberculosis Verrucosa Cutis.—This form is nearly, if not quite, identical with the "anatomical wart" of the dissecting-room. Here the papillæ are greatly elongated and enlarged, and covered with a lamellated horny layer. The interpapillary prolongations are hypertrophied. The principal changes are found in the upper layers of the corium, the papillæ, and adjacent layers. The histological appearances of tubercle are well defined. More bacilli are found, in the experience of Riehl and Paltauf, than in lupus, but less than in the miliary form. The inflammatory appearances often present are not, in the writer's experience, sufficiently constant to render their absence a point of consequence. The reader has found the bacilli as difficult of detection here as in lupus. The situation of the tuberculous neoplasm offers the chief anatomical characteristic, and is the superficial seat of the process. The process should be separated from lupus.

AMERICAN LARYNGOLOGICAL SOCIETY.

(Continued from p. 359.)

Second Day, Wednesday, September 23d.

Nasal Papillomata.—A paper with this title was read by Dr. Jonathan Wright, of Brooklyn. In several hundred cases of nasal growths of various kinds, he had seen only one true case. Hoffman's statement as to their great frequency, he could not at all agree with. The term papillomata was an indefinite one, and was used by different men to refer to different conditions. Even Virchow has contradicted himself, verbally at least, in the discussion of this class of growths. A true and preferable term would be papillomatous fibroma. This was a growth with an epithelial covering, into which projected a vascular loop, supported in turn by a fibrous stroma. The microscope alone could therefore settle the diagnosis. Papilloma pure and simple is correctly used in reference to a surface phenomenon. Hoffman had used the term adenoma papillæ, but many growths of this nature were simply masses of chronic hypertrophic inflammation. They are masses of glandular hyperplasia with increased vascularity. These are matted together by mutual compression, and often have a crumpled surface. There are various degrees of the process. Most true papillary fibromata grow from the cartilaginous septum or from the floor of the nose. Hoffman's masses grow most frequently from the inferior turbinated. This difference in site is of clinical service in differential diagnosis, but the latter can be definitely settled only by the microscope. We should always remember that the mucocutaneous junctions are the favorite seat of epithelial pro-

liferations, benign, specific, or malignant. The symptoms and treatment of the condition are obvious.

Dr. Mulhall, of St. Louis, reported one case definitely decided by the microscope to be a true papillary fibroma.

Dr. Shurlev, of Detroit, called attention to the fact that these tumors well illustrate the laws of evolution in their development. The process of growth is essentially a vegetable one.

Dr. Jarvis, of New York, had found that chromic acid, when applied to the base of these growths after removal, always caused a deep eschar and a permanent cure; while, applied to other intra-nasal conditions, such as septal enlargements, hypertrophies, polypi, etc., there is always more or less return.

Dr. Mackenzie, of Baltimore, had had patients with chronic hypertrophic rhinitis who in blowing the nose would expel small bits of flesh. These bits showed a transitional state between a hypertrophic and an atrophic condition. The patients were temporarily relieved, but sclerosis was slowly setting in, and gradually caused considerable atrophy. Hence their last state was worse than their first.

Dr. J. Solis Cohen, of Philadelphia, also discussed the paper.

A Study of a Case of Nasal Tuberculosis was the title of a paper by Dr. E. L Shurly, of Detroit. The case was that of a monkey who had a profuse purulent discharge from one nostril, in which tubercle bacilli were found. There was no cough or dyspnœa. It had occasional fever, and desired only fluid diet. On a treatment of chlorine gas inhalations, and the use of sodium chloride water, it rapidly improved, and the discharge and relative number of the bacilli lessened. Cessation of treatment caused a relapse and increased bacilli. After a while the animal was killed, and a post-mortem examination was made. No tubercle tissue was found anywhere. There was chronic submucous hypertrophy in the nose. Thrombi were found in spleen and lungs, while the liver and kidneys showed new connective tissue as in syphilis.

The cause of this suppuration was probably due to some parasite or foreign body. The pus probably came from one of the sinuses of the region. It was surprising that the bacilli, having found an accidental culture medium, should not have invaded the organism at large and set up typical changes. Slides illustrating the nasal condition were exhibited. Dr. Shurly thought that the case threw some doubt on the generally accepted relation of the bacillus to tubercular tissue.

Cyst of the Middle Turbinated Bone.—A paper with this title was read by Dr. Charles H. Knight, of New York. This condition was frequent, but little noticed. His patient was a middle-aged woman whose right nostril was occluded by a growth resembling in appearance a myxoma, but it was hard and resistant. There was a deviation of the septum and a left hypertrophic rhinitis. It was removed with cocaine by the cold wire snare, and a good recovery ensued. The symptoms of this condition are caused by the pressure of the expanding cyst, and consist of hemicrania and various neuroses of the fifth pair of cranial nerves. If myxomata coexist there is danger of empyema of the antrum. The inferior bone is rarely affected, only one such case having been reported, also one affecting the superior turbinated. This condition is rare under twenty, and is more common in middle-aged women. A differential diagnosis is necessary for myxoma, osteoma, and mucocele of the ethmoidal cells. Cysts have, of course, a very thin and fragile wall, and are, according to Zwillinger, translucent.

There are two theories regarding their formation. The first regards them as due to a rarefying osteitis. The other, advanced by Greville McDonald, considers them as commencing in a hypertrophic rhinitis. After a while there is an osteophytic projection lengthening the bone, which then begins to curl upon itself, and finally meeting its body, forms a closed cavity lined by mucous membrane. Hence there is a secretion of mucus or pus if disease involves the interior. The interior is lined with ciliated epithelium.

Dr. Knight considered the second theory the more satisfactory, though it was difficult to explain by it some of the conditions sometimes found. The cysts are always broken in removal. Symptomatology was obvious.

Dr. Wright gave the history of a case where there was no ciliated epithelial lining. The contents were grumous, due probably to the hardening fluids employed.

Dr. W. E. Casselberry, of Chicago, reported a case of myxoma with calcareous degeneration of the outer portion, producing a very thin shell filled with a mucous material. It grew from the middle turbinated body.

Various Forms of Disease of the Ethmoid Cells.—Dr. F. H. Bosworth, of New York, read a paper with this title. During the past five or six years he had seen 27 cases, which he divided into the following categories: 1. Myxomatous degenerations without purulent discharge, 5 cases. 2. Extra-cellular myxomatous degeneration with purulent discharge from the ethmoid cells, 4 cases. This form might be a later stage of the first. 3. Purulent ethmoiditis with nasal polypi, 13 cases. Of these 7 had also antrum disease. 4. Intra-cellular polypi without purulent discharge. 3 cases. 5. Intra-cellular polypi with purulent discharge. 2 cases. The fifth was a later form of the fourth.

Dr. Bosworth regarded this as a good and practical division of the large number of cases now grouped under the indefinite title of "ethmoid" disease. He could not agree with Woakes's theory of necrosing ethmoiditis. He rather believed just the opposite. The hiatus semilunaris was a common meeting-point for the secretions from the antrum and anterior ethmoidal cells. Nasal polypi were apt to grow here and dam up the secretions, thus causing them to assume a purulent character. By carefully tracing the source of the pus and remembering anatomical relations, the exact seat of disease could be determined. The treatment was to remove the polypus and drain thoroughly all the cavities affected. Sphenoid disease, from its posterior situation, generally discharged its pus into the naso-pharynx, while posterior ethmoidal suppuration discharged above the middle turbinated, at the junction of the middle with the posterior third. A small spoon curette had given the best results in scraping the sites of disease.

Dr. Jarvis advocated the removal of the cap of the middle turbinated in multiple myxoma. Small masses of this nature might exist in the cells themselves. We may have a form of acute ethmoiditis independent of nasal polypi. The clinical history of such a case was given. There was retention of secretion, subocular enlargement of the lymphatics, and some evidences of septicæmia. A removal of the turbinated body by drilling relieved all symptoms. Non-myxomatous ethmoiditis is often due to congenital defects or displacements of the nasal septum, causing a lateral impaction preventing free drainage.

Dr. Wright narrated a similar case following a quinsy. He thought that acute cases generally recovered without operative interference.

Dr. Mulhall, of St. Louis, said that the disease often required desperate measures. The curette had given him much satisfaction.

Dr. Jarvis remarked that he had never seen sepsis follow the use of the cold wire.

Dr. Mackenzie also discussed the paper.

The Radical Treatment of Nasal Myxomata was the title of a paper read by Dr. W. E. Casselberry, of Chicago. Two-thirds of all these bodies were under the middle turbinated bone. They rarely developed from flat surfaces, but generally from free edges, mucous membrane soddened by profuse secretions furnished a good soil for their growth. The middle turbinated bone lies in a region of free edges, and hence the partiality of the condition for this area. To remove these masses it was

sometimes necessary to take off the anterior inferior end of the turbinated bone. The site of growth should be touched with the cautery.

There is some danger from too radical procedures in this direction. There is danger of cerebral mischief, as several cases of the latter had been reported from intra-nasal operations. The writer used a curved scissors, and sometimes cutting punch forceps.

Dr. Sajous, of Philadelphia, had used the rongeur forceps with advantage. He took off the tip of the bone and thus obtained room to get at the myxomata higher up. He used a glass-covered electrode with a bent and flattened tip of platinum, and could scrape as well as burn with it.

Dr. J. Solis Cohen commended the use of witch-hazel solutions, one to four, for intra-nasal use after the removal of polypus. He had found that it prevented their recurrence.

Dr. Bosworth had no faith in medicinal applications, and condemned the use of the cautery.

Dr. Roe used a bow saw with its cutting edge at right angles to the handle, to saw off the tip of the bone.

Dr. Rice, of New York, thought there was danger of secondary atrophic rhinitis if we removed too much tissue.

Dr. Mulhall favored the use of the cautery at a white heat. So used, it was practically harmless.

Drs. Asch, of New York, and MacKenzie, also spoke on the paper.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

(Continued from p. 360.)

Second Day, Wednesday, September 23d.

The Sputum in Pulmonary Phthisis. — Dr. E. L. Shurley, of Detroit, Mich., read the first paper of the day's meeting, entitled as above. The results of the series of studies and scientific experiments embodied in the paper were admitted as throwing no new light upon the first step in the pathogenesis of tuberculosis, but as demonstrating the varying degrees of strength and viability, with resulting intensity of infection from different cultures of bacilli, they afford a basis for the explanation of varying degrees of susceptibility in individuals to the development of tuberculous disease. The method of experimentation observed by the writer, elaborately outlined in detail, were: 1st, Cultivation under different conditions and in different media; 2d, inoculation with control experiments

Drs. Tyndall, Gihon, and Williams participated in the discussion which followed, the latter confirming from personal experience the statements as to the varying degrees of viability of different chemical extractions of tuberculous tissue. He believed that the only explanation of variations in the action of different cultures of bacilli was to be found in the viability and violence of action of the bacillus itself.

Surgical Treatment of Acute and Chronic Empyema. —Dr. Maurice Richardson, of Boston, read a paper upon this subject. Drainage, he considered of equal importance with asepsis or antisepsis. The most desirable object in such cases was to obtain lung expansion, and this can be best accomplished by drainage. Empyema is essentially a surgical affection, though aspiration had occasionally proven efficacious. It was often, however, dangerous, in that it led to delay in adopting surgical measures which should be resorted to early, in order to prevent adhesions and interference in consequence with expansion. The author's method of preparation for operation to secure drainage involved the most thorough aseptic and antiseptic precautions. The field selected should be scrubbed twenty-four hours previously with soap and water and a hot-water poultice of aseptic cotton batting should be applied for twelve hours, followed by a similar poultice rendered aseptic with corrosive sublimate, which should remain *in situ* until immediately preceding the operation. He did not think general anæsthesia advisable, as it interfered with the voluntary coughing of the patient during evacuation, which was important in assisting in the expulsion of pus and in expanding the lung. The point of incision was a matter of election. He usually selected the fifth or sixth interspace in the axillary line. In cases which were chronic, the cavity being closed by collapsing walls, drainage could be best accomplished by inserting the tube high up. It is good policy to consider all cases as chronic. No advantage resulted from cutting through the latissimus dorsi and several objections could be urged. Toward the front of the axillary line the proximity of the heart was objectionable. He prefered to all methods that of a free incision two or three inches in length. Drainage-tubes should be at least three-eighths of an inch in diameter, two or more in number, fastened with a shield and supplied or not with a rubber-tissue valve according to the condition present. Valves were of advantage to create vacuum pressure where ordinary respiration fails to produce proper lung expansion. Rubber is the best material for drainage-tubes. The tube should remain in position until forced out by the filling out of the thoracic cavity, rendering it impossible to replace them. To remove clots, etc., at time of operation pure boiled water is best. Irrigation he considered unnecessary unless there was an offensive odor to the discharge. If odor existed, he had found a solution of styron, 1 to 200 beneficial. The ordinary antiseptics were dangerous, as the pleural membrane absorbed readily. He had seen systemic carbolic-acid poisoning, not only from the use of irrigation with carbolic solution, but from the application of carbolized gauze over the incision wound.

Hemorrhage could be often arrested by the pressure of the drainage-tube upon the margin of incision. The sound of ingress and egress of air immediately after operation afforded an indication of a probable favorable result. Cases of long standing and tuberculosis cases were unfavorable in prognosis. In chronic empyema resection of the ribs which was indicated was of value not in proportion to the extent of rib removed, but to the number re sected. Six or eight ribs could be resected in certain cases with proportionate advantage. The contraction of the chest-wall thereby accomplished was more satisfactory than when a smaller number were resected. The length of rib removed should be equal to the depth of the cavity. He had not tried the suggestion emanating from the Harvard school of anatomy, to force together the ends of the resected ribs and wire them. The immediate results of the operation of incision and drainage, if properly done, were always gratifying if not curative. He had lost two cases in fifteen operations, death occurring from recurrence and tuberculosis.

Dr. Loomis indorsed the view that surgical incision was *the* rational and only satisfactory treatment in empyema. In acute empyema a cure was not difficult, provided the opening was sufficient. If the case was chronic he considered the prognosis as varying according to the amount of plastic or fibrous matter found in the cavity as a result of the pus-forming process.

Lymphotism.—Dr. F. H. Bosworth, of New York, in a paper with this title described lymphotism as a condition of disease occurring in early life characterized by a glandular involvement which might exist widely, but which usually manifested itself in the cervical region, the upper air-tract, and the fauces in adenoid enlargements, tonsillar hypertrophies, etc. There was, as a rule, an associated anæmia, more or less profound headaches, interference with normal respiration, and consequent imperfect assimilation from defective oxidation. The prognosis he considered favorable provided the condition is recognized as one requiring attention and proper treatment inaugurated. Constitutional treatment is most effective, and the iodide of iron, in the form of a syrup or in Blancard's pills, the remedy par excellence. The

dose should be at least two grains of the iodide of iron thrice daily.

Dr. Jacobi of New York, did not think lymphotism existed as an entity in disease, but that it was a secondary process originating in a local irritation. Cervical adenitis, from stomatitis, eczema, scrofulous glands, so called, of the omentum from hyperæmia due to diarrhœa, and other similar conditions, were cited as examples of local irritation acting as a cause of the secondary condition. The primary irritation should be relieved and the lymphotism prevented.

Dr. Darlington, of Arizona, related an experience with fifty cases of apparent epidemic adenitis of the cervical glands of undetermined etiology.

Histological Changes which Take Place in the Lungs in Cured Phthisis Pulmonalis and the Influence of Diathesis in the Development of Such Changes.—In a paper entitled as above, Dr. A. L. Loomis, of New York, described a series of pathological observations made upon the records of 524 autopsies done at Bellevue Hospital, eight per cent. of which were found to represent instances cured of tuberculous disease though the patients died of non tuberculous affections. The records of this table of cases were prepared by Dr. Henry P. Loomis. As regards the lesions which may be regarded as evidence of cured phthisis, patches of induration at the apex of the lungs, for a long time considered characteristic, have been demonstrated as the result, at times, of other causes of irritation than tubercle. Masses of fibrous tissue in the lungs, until after the discovery of the tubercle bacillus, were not positively demonstrable as of tubercular origin. Of the 44 cases observed, forming the basis of his paper, in 38 the gross appearance of the affected lung showed firm adhesion to the costal pleura with puckering and depression of the adherent surface; sections showed varying numbers of fibrous nodules scattered through the lung apex, situated in most instances just beneath the adherent surface, and continuous with the thickened pleura. A few were in the central portion of the upper lobe, connected with the pleural surface by dense bands of fibrous tissue. Soft cheesy or calcareous masses were usually found in the central portions of these nodules, and in six small closed cavities occupied the centre of the larger nodules. A linear cicatrix was found in a few nodules, marking the site of a healed cavity. Lamellæ of less dense fibrous tissue, often traversed by contracted, obliterated, and dilated bronchi and impervious blood vessels, were found immediately around many of these nodules. An emphysematous condition was observed in the surrounding lung-tissue, which appeared normal. Two instances showed the entire upper lobe of the lung transformed into a homogeneous fibrous mass. More or less deep pigmentation was noted in the fibrous tissue of the nodules. On microscopical examination of these nodules, more or less completely organized fibrous tissue was observed as the prominent histological change.

In many, at the edge of the tissues destroyed by the tubercular process, new connective tissue could be seen just developing, and the fibroid process evidently originated in one of these ways: 1, By round-cell infiltration of the interlobular connective tissue; 2, by round-cell infiltrations of the alveolar walls; 3, by round-cell infiltrations around the vessels and bronchi which became contracted and obliterated by the fully developed fibroid growth. In some sections pleuritic fibrosis seemed to be the first change, and in all lines of fibroid tissue could be traced from the nodules to the pleura. One condition was so constantly present as to lead to the conclusion that it was essential, a condition of intense hyperæmia always surrounding the tubercular areas where recent fibroid processes were active. The developed fibroid masses were also found studded with new capillary vessels. The different elements composing tubercle could not be determined. Tubercle bacilli could only be found in one or two specimens. Inoculation experiments with the contents of the nodules upon rabbits gave uncertain results, producing tuberculosis in certain cases and no reaction in others. General tuberculosis followed in no case. The conclusion from observations made was that the only method of arresting tubercular processes in the lungs was by the development of fibroid processes in and around the tubercular areas. The occurrence of this reparative process in an individual he believed to be dependent upon diathetic tendencies. The two diathetic conditions involved affecting tubercular process favorably or adversely were the fibroid and the strumous. Necrotic changes occurring in parenchymatous tissue can only be repaired by fibroid development, which must be pathological in intensity in order to be effective if the cause of the necrosis be especially powerful. Several clinical cases were cited illustrative of the antagonistic action of diathesis, especially marked in arthritic individuals who possessed a relative immunity from all forms of tuberculosis. Tuberculosis of the pulmonary type occurring in patients with a parental history of general fibrosis had a tendency to a chronic course and spontaneous cure. Of seventy cases of cured cases of pulmonary phthisis personally observed by the writer fifty-two presented marked evidences of general fibrosis. The prognosis in tuberculosis is largely dependent upon the diathesis and family history of the patient, a factor in prognosis which has been unwisely ignored since the discovery of the tubercle bacillus. A better explanation of the varying results of tubercular disease in different individuals than that of intensity of bacilli infection is to be found in the presence or absence of diathetic antagonism. Koch's tuberculin, if it has any power in arresting tubercular processes, does so by exciting around the diseased areas inflammatory processes which favor fibroid development.

In the discussion following, Dr. Jacobi said that he believed the cure of local tubercular disease to be dependent upon the development of surrounding fibroid tissue, and that this development could be assisted, he thought, by the use of certain agents having the property of setting up local irritation, if given in small doses. He had used for twenty years, as a matter of routine, in conjunction with other measures, arsenic, in the treatment of pulmonary tuberculosis, in small doses. He did not consider it a specific, but believed it of decided value. Phosphorus, given by Wagner experimentally to hasten the cure of fractured limbs in rabbits, he believed to be rather unsafe in phthisis, in that the resulting irritation was excessive.

Dr. Curtin thought that the results claimed for the treatment of pulmonary tuberculosis by injections of iodine into the pulmonary cavity, suggested some years ago by Dr. Pepper, could be explained by the development of fibroid tissue resulting from the injections. He had recently noticed, in an autopsy upon one of Dr. Pepper's patients, so treated some years ago, the same pathological conditions mentioned by Dr. Loomis.

Dr. Beverley Robinson had followed Dr. Pepper's suggestion, and had used iodine by injection into the pulmonary cavity, with modification and amelioration of symptoms as a result. He believed creosote, used as he had recommended it some years ago, to be of more benefit than any other single agent mentioned in the discussion.

Dr. Tyndall suggested that the terms destructive and constructive metabolism be used for scrofula and fibrosis.

Dr. Fremont-Smith mentioned the fact that Lannelongue explains the *rationale* of cures resulting from his method of injecting a solution of chloride of zinc in tubercular disease of joints as being the result of the development of fibroid tissue.

Dr. Jacobi saw some of Lannelongue's patients treated, and others shown as examples of curative results obtained. The strength of the zinc solution used was fifteen per cent. Proof of cure, in an absence of pain and swelling, existed in some of the cases shown as cured, but in several swelling was still present, and the patients—children from three to eight years of age—cried out with the

pain when touched. These cases had been under treatment from two to six weeks.

Dr. Williams considered the teachings of Dr. Churchill in line with the facts as elaborated in the paper read. Calcification while not identical with fibrosis is related to the arthritic and gouty diatheses. Hypophosphites were promotive, he believed, of irritative processes resulting in fibroid-tissue development.

Dr. Loomis, in closing the discussion, expressed the opinion that the sole benefit derived by tuberculous patients from creosote was through its action in promoting assimilation by assisting digestion.

Analysis of Recorded Cases of Phthisis Pulmonalis.—Dr. S. A. Fiske, of Denver, Col., read a paper with the above title, tabulating results in a large number of cases, illustrative of the modifying effects of suppurative and symptomatic treatment assisted by the climatic effects of a residence in Colorado.

Dr. Ingalls asked for an explanation of the remarkable frequency of hemorrhage as a cause of death in the cases mentioned.

Dr. Fiske stated in explanation that hemorrhage was cited as a cause of death in some cases in which it was only indirectly responsible; after a hemorrhage, the patient, who had previously improved, never rallying and becoming progressively worse. In only one case was death due directly to absolute loss of blood.

Attempts to Discover Specifics for Phthisis.—This was the subject of a paper by Dr. H. F. Williams, of Brooklyn. The present status of intelligent medical investigation in the field of tuberculosis is distinctly not in the line of attempts to discover a specific for phthisis or other tubercular disease, but toward the accumulation of agents and measures by which the disease processes may be modified and relief obtained through the upbuilding of nutrition and constructive metamorphosis generally. His observations had led him to believe that the activity of bacilli varied within wide limits, depending upon the removal of the bacilli in any given case from the original source of development. Bacilli diminished in the intensity and violence of their action by a process of self-attenuation. As to the various methods of antagonizing tuberculosis, vaunted at different epochs as having specific value, his experience led him to place great confidence in the modifying influence for good from the use of the pneumatic cabinet. By its use the lungs could be filled with aseptic air, and thus the fermentative decomposition and activity of lower types of micro-organisms could be controlled, and the activity of the tubercle bacilli in that way lessened.

Dr. Carl von Ruck, of Asheville, N.C., in the discussion which followed, stated that he had used, with much benefit in some cases, the pneumatic cabinet. It was not appropriate to all cases, and in some there were decided contra-indications to its use. Every case of phthisis required discrimination in the agent used as a remedy. The effect of the pneumatic tube was largely upon the heart and circulation, promoting a general improvement, giving better aëration to the lungs, and making more blood. It should only be used as an adjunct to other methods.

The Value of Koch's Remedy Employed as an Alterative: Reactive Fever Prevented, was the title of a paper by Dr. Frank Fremont Smith, of St. Augustine. Personal observation in Berlin and experience with his own cases in Alicia Hospital, St. Augustine, lead to the following conclusions:

1. The dose of tuberculin is a widely varying quantity, to be determined, with its rate of increase for each case, only by direct experiment.

2. The only therapeutic dose is such a quantity as arouses no reactive temperature, every reactive fever being the expression of an overdose, *i.e.*, a poisonous dose.

3. Tuberculin, when successful by fever reactive method, is so despite, not by virtue of, reactions.

4. Tuberculin by non-reactive method acts as a powerful upbuilding alterative to the tuberculous subject.

5. Cases in all stages of tuberculosis may be treated by non-reactive method without danger. To produce every second day the ultra-physiological action of tuberculin, as exhibited in fever reactions, disturbs the general equilibrium and disarranges nervous, digestive, and secretory functions, upon whose very quietude and uninterrupted activity substantial improvement is of necessity based. Experiments begun January 27, 1891, with non-reactive method, give in twelve cases uniform gains in the six incipient cases: 1st case, gain in thirteen weeks, 17 pounds; 2d case, gain in ten weeks, 20 pounds; 3d case, gain in eighteen weeks, 12 pounds; 4th case, gain in five weeks, 10¼ pounds; 5th case, gain in twelve weeks, 3½ pounds; 6th case, gain in five weeks, 3 pounds.

Second Day, Wednesday, September 23d.

The Remote Results of the Removal of the Ovaries and Tubes.—Dr. William T. Lusk, of New York, read a paper on this subject. The ovaries have been removed for the relief of local pain or for the amelioration of certain nervous symptoms. Oöphorectomy has been done too much of late. It is important to relieve the woman, but by pessaries, rest, and prolonged treatment much of the discomfort may be removed. Very often the removal of ovaries brings about a cure which might have occurred with proper non-operative treatment. The improvement is, of course, attributed to the operation. The removal of the ovaries is not without danger. It may give rise to a large number of symptoms. A woman is castrated and becomes unsexed, the menses cease, the uterus becomes small, and the vagina atrophied. Often the sexual appetite is impaired, although in many cases the woman had no sexual desire before the operation. At rare times it is increased, but most often it is diminished, and even if it is increased this increase does not last long. In a large number he observed no change after the operation at first, but afterward they all lost desire. The woman who is unsexed and has no ovaries cannot marry without an explanation, and this may either prevent the marriage, or if the couple are Malthusians they can marry anyhow. It may be said that the woman is sterile as soon as those organs are diseased, and the mere operation does no harm. He did not include such cases. A woman came to him fully prepared for the operation; he objected, she insisted; he put her on treatment. She got better, had children, and is now well. Most cases of tubal swelling yield to treatment. Mr. Tait has started a collective investigation committee to see when an operation is necessary. He reported sixty-five cases where the uterine appendages were removed. The removal of the ovaries for hysteria he considers as malpractice. Dr. C. C. Lee reports that loss of appetite in his experience followed this operation. The loss of her ovaries does injure the woman. He tries everything before he begins to think of operation. The successful removal of an organ is not a triumph of art, but a confession of defeat. Many cases resulted in mental derangement. This may have occurred without the operation, but it is not likely. In some cases this is incurable, in some cases curable.

Dr. Wharton Sinkler said that it makes a difference whether the operation has been done for diseased ovaries or whether the ovaries have been removed for some disordered condition of the nervous system, such as hysteria, epilepsy, or insanity. The consideration of the after effects of the operation is very important and everyone recognizes this importance. Most operators know little about the patients after the operation. They go back to their family physicians or to the neurologist. Was the operation for the relief of those organs? The operation is the same whether the organs are diseased or healthy, but the age of the patient makes a difference. Before puberty the changes in the patient's characteristics are

great, but after this they are not so great, they are much like the changes occurring at the climacteric period. We have the sign of change of life, the flushing and usual disturbance of the heart's action, rapid pulse, atrophy of the internal genitalia. But there is no masculine change as some have asserted. She becomes fleshy, but not often stouter than before her illness—that is, with some exceptions. She is thus unsexed, and more than this, she has a series of various nervous troubles. This is due to cerebral hyperæmia. There is mental depression or mild melancholy; in others there is a mild insanity. T. G. Thomas reports six cases of melancholia after these operations and many others are witnesses to the fact of mental disturbances.

Insanity follows a large number of hysterectomies; not ten per cent., as some have said, but a large number. The general opinion seems to be that the sexual desire is not affected by the operation of castration. Dr. Weir Mitchell reports three cases of cure from ovarian trouble by rest, marriage, etc., cases which had been examined by eminent gynecologists, and pronounced as necessary for operation to be cured. These got entirely well without an operation. Not weeks, but months of rest should be tried. The ordinary insanity is not affected by this operation, but monthly insanity, coming on at the menstrual period, has been cured by operation. Pelvic pain has been cured by operation, but such pain has returned in the stumps of the ovaries months afterward.

Dr. Putnam, of Boston, thought it was not right to treat neurasthenia by operation. Hypnotism has been tried with success, and has done as much good as operation. He does not believe that neurasthenia is a definite disease, but is due to many causes.

Dr. S. Weir Mitchell, of Philadelphia, had seen many cases of removed ovaries which should have never been touched. The gynecologists were the ones who were to blame and who did the most harm. We should be careful and have some charity. Every new medicine and every operation produces some excesses. The bromides did that when they were first used. These cases have not gone on long enough to give us remote histories. The statistics are not worth much. Most men made the mistake of operating without deliberation and conservatism. A young man should never undertake such an operation without good advice. In a long life and experience he had only seen eighteen cases in which he had considered operation necessary. There may have been others which passed from his hands to an operator, but he had only found it necessary to operate on these eighteen. Of these there was no death. Every case he sent to a surgeon was carefully prepared for weeks and months beforehand. The danger is now of operating too quickly after seeing the case. A long course of treatment may render an operation unnecessary by curing the patient or better fitting it for the operation if it is necessary. The practical abolition of the death penalty in surgery has produced too much liberty, and made men reckless and indifferent, or too ready to operate without sufficient consideration. He cited four cases, of which three had been doomed by eminent gynecologists to lose their ovaries and they all recovered and bore children.

Dr. W. T. Gairdner, of Glasgow, said that they do not operate so frequently in Glasgow. He was much pleased with Dr. Lusk's paper and mentioned a typical case that got well without operation.

Dr. C. C. Lee, of New York, was not so opposed to operation as the author. Had collected statistics to show that his operations have been of permanent good.

Dr. W. T. Wathen, of Louisville, had operated much in time past, but was not doing so much now. He was much pleased with Dr. Lusk's paper and agreed with him on many points.

Dr. W. T. Lusk, in conclusion, said that all seemed to have gone over the same ground. His desire was to show the necessity of reducing the number of operations.

Nerve-stretching in Inveterate Cases of Trigeminal Neuralgia.—Dr. James Stewart, of Montreal, Can., gave a report of a series of cases of severe neuralgia in different parts of the body cured by nerve-stretching. It relieved in a majority of cases but was not permanent in five per cent. after cure and should be repeated. Several branches of the same nerve should be stretched, but not all at once, but after the lapse of several days.

Diseases of the Kidney, Popularly called "Bright's Disease."—Dr. Francis Delafield, of New York, read a paper with this title. He said that the term "Bright's Disease" is no longer of use, except as a popular expression; there is no such disease. At the present time a working classification of renal diseases is made most easily according to the character of the morbid process. Such a classification would be as follows: Acute congestion of the kidney; chronic congestion of the kidney; acute degeneration of the kidney; chronic degeneration of the kidney; acute exudative nephritis; acute productive, or diffuse, nephritis; chronic productive, or diffuse, nephritis, with exudation; chronic productive, or diffuse, nephritis, without exudation.

Various Tests for Albumin.—Dr. A. H. Smith, of New York, presented a communication on this subject. He spoke of the various kinds of albumin in the urine, the difficulty of separating them, and the delicate tests for them. He showed a series of tests made with Merck's chemically pure serum-albumin dissolved in pure water, and believed that all urine contained albumin. He used heat, nitric acid, ether, and chloroform.

Dr. W. T. Councilman, of Baltimore, agreed in part with Dr. Delafield. He had noticed that there was a great similarity of lesions in kidney disease. He made two classes, focal and diffuse lesions. There must be some alteration of the blood in character, etc., for it to get into the urine. The focal lesions are those which reach the kidney in a soluble form or bacteriological lesion. They are brought to the kidney and deposited in it. Another class is that in which the lesions are diffuse, being in the blood, and are scattered over the kidney, as in the lesions of the infectious diseases, the lesions which can come in consequence of a chemical substance used in nature which we do not understand. These can also enter the kidney by the ureters, producing certain changes in it.

Dr. V. Vaughan, of Ann Arbor, Mich., thought that Dr. Delafield's paper showed a step in the right direction. Dr. Smith should remember that Merck's chemically pure serum-albumin was not chemically pure at all, but was simply made from coagulated blood, and contained a large amount of the substances which vitiated his tests. He did not believe in making such delicate tests. It was better to miss the presence of albumin occasionally than to turn down a healthy man in a life insurance examination because we find a coagulable substance by one of these delicate tests. If the peptones are in the blood they must be got rid of, and hence when found in the urine it is a natural process of nature in getting rid of them.

Dr. J. P. Crozier Griffiths, of Philadelphia, said that in the preparation passed around the chloroform had not precipitated the substance, but had formed an emulsion with it, and he could get the same emulsion in a less marked degree with water alone.

Dr. W. T. Gairdner, of Glasgow, spoke of the importance of a review of our nomenclature in medicine. He wanted no disease named for him, spoke of the various forms of kidney disease, and said that heat and nitric acid were the best tests for albumin.

Dr. Vaughan, of Michigan, said heat, nitric acid, and an acetic acid with the ferrocyanide of potassium, were the best tests for albumin in the urine.

Dr. A. H. Smith said, in conclusion, that his work was only to bring the most delicate tests before the Society. He already knew what Dr. Vaughan had told him.

AMERICAN ASSOCIATION OF ANDROLOGY AND SYPHILOLOGY.

(Continued from p. 364.)

SECOND DAY, WEDNESDAY, SEPTEMBER 23D.

A Case of Excision of Stricture and Urethroplasty for Radical Cure.—DR. EDWARD L. KEYES, of New York, opened to-day's session by reading a paper with this title. He stated that the radical cure of stricture in the deep urethra is still an open question. The question has been measurably solved for the anterior urethra, chiefly through the energy and zeal of Professor Otis, and his persistent advocacy of extensive dilating urethrotomy. The same solution has not yet been proved to hold in the case of organic strictures of the deep urethra, nor has any other single rule been advanced to cover all cases. The author classified deep organic strictures into three groups, the soft, the cicatricial, and the inodular. The soft stricture is not uncommon, and is capable of immediate dilatation up to the full urethral calibre; it can be recognized by a peculiar feel in passing a blunt instrument into the bladder. Dr. Keyes stated that this form of stricture can be permanently cured by continued dilatation. He then gave the history of a case of radical cure of deep urethral stricture of great extent and long duration, complicated by perineal fistula, and by some tissue, apparently inodular. The stricture was first laid open upon a whalebone filiform guide, and then the dense, fibrous tissue composing it was cut out; the fistulous tracts were also dissected out and a plastic operation performed, taking a large piece off the inner layer of the prepuce for that purpose. This piece of tissue was thoroughly disinfected and sutured into place in the roof of the gap left by the excised stricture. The perineal wound healed very rapidly, and recovery was uninterrupted.

MR REGINALD HARRISON, of London, stated that while he had but a very limited experience in the treatment of strictures by the process of excision, and practically none so far as it relates to excision with grafting, he thought that Dr. Keyes' paper presented a method of treatment which is likely to be of considerable value in deep urethral strictures. Mr. Harrison stated that while in Paris he had seen M. Guion treat two or three cases of traumatic stricture by excision. Instead of doing a plastic operation, however, M. Guion had closed the wound by three layers of sutures.

The discussion of this paper was continued by Sir William MacCormac, of London, Dr. John P. Bryson, of St. Louis, and Dr. L. Bolton Bangs, of New York.

A Contribution to the Surgical Treatment of Ruptures of the Bladder, by DR. ARTHUR P. CABOT, of Boston. In his paper Dr. Cabot considered the conditions of extra-peritoneal rupture of the bladder. The usual symptoms of rupture of the bladder, the author stated, were tolerably distinct, and the lesion can be demonstrated almost beyond doubt by the physical test of the injection of fluid or air. This test might fail when the rent is very small, or when there is a valvular closure of the bladder wound. Some writers, the reader stated, advise that cases of extra-peritoneal rupture should be treated by simple drainage of the bladder, either through a perineal wound or by a retained catheter. This plan Dr. Cabot considered insufficient drainage for the urine which has already escaped into the tissues, or for the pus and masses of sloughing tissue which are certain to follow from the contact of urine. It is important that the operator should know where the rent is, and in what direction the urine is forcing its way through the loose peri vesical connective tissue. When this knowledge is obtained he can make an opening into the extravasation from the nearest available point on the surface, and establish the most direct drainage possible. An incision into the prevesical space, as suggested by Mr. Rivington, is applicable in cases in which the rupture is in the front wall of the bladder, just above the prostate, and in which the effusion is small or circumscribed. Another plan proposed in doubtful cases, the author stated, is to make a median cystotomy, and with the finger in the bladder to search for the rents; but this method has in some instances proved unsuccessful. The best method of obtaining a knowledge of the condition of things in doubtful cases of extra peritoneal rupture, Dr. Cabot stated, is by opening the abdominal cavity and so getting an opportunity to thoroughly inspect and palpate the parts about the bladder. The reader then gave the history of a case where an extra-peritoneal rupture of the bladder occurred during the operation of litholapaxy, which was at once discovered and treated by opening the abdomen; and he suggested that in all cases where a rupture is made out, prompt action should be taken and a laparotomy performed, excepting where it is evident that urine is extravasated in the prevesical space, where a supra-pubic incision is sufficient; or cases where the shock is so severe that the patient cannot bear more than the median operation.

SIR WILLIAM MACCORMAC, of London, stated that Dr. Cabot, in his excellent paper, had covered a great amount of ground and given many valuable hints. The diagnosis of extra-peritoneal rupture, was in many cases much more difficult than that of intra-peritoneal. The speaker thought that one of the methods of diagnosis mentioned by Dr. Cabot, namely the injection of fluid, might add to the difficulty rather than diminish it, and that he considered the injection of air preferable. Another point of diagnosis which is mentioned in all the text-books on this subject, namely, the extreme shock, he has found entirely absent in two cases which came under his observation.

DR. L. BOLTON BANGS, of New York, suggested that perhaps the cystoscope could be used to advantage in locating rents in the bladder.

DR. KEYES said that, on account of the bleeding, the cystoscope is of no use in these cases.

DR. CABOT called attention to the fact that the ruptured bladder would be collapsed, and so not suitable for the cystoscope.

On the Use of Salicylic Acid in the Treatment of Certain Forms of Cystitis, by DR. JOHN P. BRYSON, of St. Louis. He stated that about three years ago a student by mistake mixed one ounce of a two per cent. solution of salicylic acid in glycerine with five ounces of water for the purpose of washing out the bladder of a patient with chronic exudative cystitis, and who had previously had his bladder irrigated with the standard borax solution in glycerine and water without material benefit. The returning fluid was milky in appearance, and a second ounce was thrown in before the mistake was discovered. The patient returned the next afternoon to report that he was much better, and to ask that a similar injection be given, which was done. From this time a salicylic acid solution has been in common use at the genito-urinary clinic of the St. Louis College, in similar cases, with marked benefit. It is particularly useful in the more chronic cases where the surface of the bladder is covered with a thick or a tenacious protection, made up of mucus and necrotic epithelia. The salicylic acid has the power of dissolving or loosening the epithelial cells, and the bladder is then in a proper condition for the application of other remedies. The use of the salicylic acid solution is not of equal service in all cases of cystitis, and is distinctly contra-indicated in some. In acute cystitis, with thin exudation, it is not necessary. Where there is ulceration with a disposition to bleed it is harmful. It is also harmful in tubercular disease, and in old prostatic cases, with saculated bladders.

DR. EDWARD R. PALMER, of Louisville, Ky., stated that Dr. Bryson had related this incident to him a year ago, and that since then he has had considerable favorable experience with the use of salicylic acid in cystitis. He wished to say, however, that in using Piersch's solution—which is a combination of salicylic and boracic acids—the patients often complained of severe pain.

Dr. L. Bolton Bangs, of New York, stated that he was very grateful to Dr. Bryson for mentioning this method of cleaning out the bladder. His experience with the use of Piersch's solution was in accord with that of Dr. Palmer. He supposed the strength of the solution is somewhat a matter of judgment.

Dr. James P. Tuttle, of New York, stated that he has used Piersch's solution for the past three or four years for irrigating the bladder, and he desired to thank Dr. Bryson for informing him why he gets such good results in such cases.

Undetected Stone, by Dr. William H. Hingston, of Montreal. Dr. Hingston stated that the difficulty sometimes experienced in locating a stone in the bladder is familiar to all surgeons. The most careful exploration may fail to reveal it. In examination for stone, the author stated that the bladder should be partially filled, and the patient can be made to empty it during the exploration, with the hope that the calculus, if there is any, will strike against the instrument. The slight difference in specific gravity between the calculus and the turbid fluid allows the stone to float about, and in that condition the sound or searcher does not elicit the characteristic "click" sought for.

Dr Edward L. Keyes, of New York, stated that Dr. Hingston, in his paper, had not alluded to the washing-bottle and the small tube for the purpose of detecting stone. Another method is the education of the finger to appreciate the gritty feeling, which he considers more important than the "click."

Dr. L. Bolton Bangs said that he was in some cases enabled to detect stone in the bladder by means of the cystoscope.

Note upon a Possible Service to be Expected from Diuretin in Genito-urinary Surgery, by Dr. Edward L. Keyes, of New York. In his paper, Dr. Keyes stated that outside of the usual complications liable to attend any cutting operation, the surgeon who deals with the genito-urinary tract has to contemplate, and, if possible, guard against that other mysterious concomitant of operations upon the urethra and bladder known under various names and often called urinary fever. The theories about it are numerous. It exists and is feared by the surgeon. To prevent urinary fever, the author stated, various things have been done, and among the drugs used for this purpose are aconite, pilocarpine, and quinine. These drugs, Dr. Keyes considers of very little value to prevent the complications feared. Local urethral antisepsis with boric acid, benzoate, etc., he also considers to be very much overrated. Dr. Keyes then gave the history of a case which came under his observation last June. An operation was performed to take a large stone from the bladder of an old gentleman, and at the same time remove an outstanding third lobe. The outlook of the case after the operation was desperate, and before the patient recovered from the anæsthetic he was given ten grains of diuretin, and this dose was frequently repeated. This patient recovered, and since that time Dr. Keyes has used diuretin in every case of urethral or bladder operation falling under his hands. He gives sixty grains of salol a day for forty-eight hours before operating, and on the day of operation begins giving ten grains of diuretin every four hours, continuing it for forty eight hours. The author stated that while the use of diuretin in these cases must still be considered in the light of an experiment, he desired to say that since employing it he has never seen a chill or suppression of urine following operation. Diuretin, Dr. Keyes explained, is a combination of theobromine and salicylate of soda; it is a free diuretic and does not irritate the stomach nor depress a weak heart.

Encysted Stone, Complicated with Growths of the Bladder.—This contribution, by Dr. C. H. Mastin, of Mobile, was read by the Secretary. The paper gave the history of a case in which a growth was spontaneously expelled from the bladder eleven days after operation. Specimens were shown.

AMERICAN ORTHOPEDIC ASSOCIATION.

(Continued from p. 365.)

Second Day, Wednesday, September 23d.

Atrophy in Joint Disease.—Dr. E. G. Brockett, of Boston, said that the atrophy in joint disease is usually regarded as the result of nerve influence, *i.e.*, as reflex, the theory being practically that of Vulpian. The speaker claimed that this is not sufficient to explain the condition. If from this cause, the degree of atrophy should bear a relation to the severity of the disease or to its duration, and those structures in the neighborhood of the joint should be most affected. But it varies within wide limits, not bearing a constant relation to the severity, to the duration, or to the amount of pain. It is, however, most strongly influenced by the amount of use, as seen by its appearance in mild cases treated with immobilization, in the uniform distribution over the entire limb, and in its relation to the amount of use given the limb. The continuance of its influence is seen in the lack of development, involving uniformly all parts of the limb, and the proportion of this to the amount of freedom permitted. The facts are that the degree of the atrophy, which always occurs, does not bear a constant relation to the disease, but is chiefly determined by the amount of use permitted the limb; that this same atrophy occurs under other conditions which impair the use of the limb, but not occasioned by disease; that this atrophy is nearly, if not quite, evenly distributed over the entire limb; that during the period of growth the loss of development extends to the whole leg, and bears a relation to the degree of its confinement.

Syphilitic Spondylitis in Children.—Dr. John Ridlon, of New York, said that the symptoms of inflammation of the spinal bones appeared to come on more rapidly, and the suffering and disability were often more intense, than in tubercular spondylitis. When located in the dorsal region, the kyphos usually developed rapidly, and presented a comparatively sharp angle; in the lumbar region lordosis was marked, and psoas contraction, and not infrequently abscess, appeared before any angular deformity. Spondylitis, when associated with chronic disease in some distant joint, or with disease in some other part of the spine separated by a healthy area, and when found in connection with any of the well-recognized lesions of hereditary or of tertiary syphilis, should be given the benefit of the doubt, and be treated with large doses of mercury and iodide of potash

Pott's Disease and Pregnancy.—Dr. T. Halsted Myers, of New York, after considering the malformations of the pelvis and abdominal cavities dependent upon Pott's disease, said that inasmuch as the indication for treatment of Pott's disease was the removal of the weight of the trunk from the bodies of the diseased vertebræ, the mechanical effect of a weight placed anteriorly would surely tend to a most disastrous crushing together of these vertebræ already softened by disease and totally unable to sustain even the ordinary weight of the body. The probability of abscess formation, therefore, by the weight alone of the gravid uterus is necessarily increased. The danger of rupture of already existing abscess or precipitating pressure paralysis is aggravated. During gestation a hyperæmic condition of the cord and its membranes and of the pelvis is thought or known to exist, and the effect of this on disease of the vertebræ must be pernicious.

Of thirty-one married women observed, ten are known to have died from causes directly connected with the disease; of sixty-two unmarried women over sixteen years of age, but two are known to have died.

My cases show very plainly that in cured cases no injury has been done, and it is exceedingly rare, if it ever occurs, that the tubercular process is rekindled by the traumatism of labor. On the other hand, the cases in which pregnancy complicated active disease of the spine give us no uncertain warning, and in view of them I

should advise the termination of pregnancy at the earliest possible date.

Paraplegia in Pott's Disease.—Dr. E. G. Brackett, of Boston, considered the expectant treatment of this form of paralysis, gave the histories of four cases treated with extension from head and foot fixation, illustrating the claim that this treatment often introduces an improvement even in old cases. The following conclusions are made: In this paralysis recovery may be looked for even after its persistence for a year and a half. Treatment by fixation and extension is often attended by decided improvement, and should be given a thorough trial before resorting to radical means. The improvement is usually early, but may not appear until after a few months. Most careful attention to detail is necessary to secure a well-adapted support, and even a continuous attempt at extension. Treatment should be persisted in until the use of the limbs has become well established.

Pressure-Myelitis in Pott's Disease.—Dr. A. Hoffa, of Würzburg, Germany, said that recent microscopic researches have shown that there is no true inflammation of the spinal cord. (Microscopic preparations were exhibited to illustrate this.) When the tubercular growth in the body of a vertebra perforated the posterior surface and destroyed the periosteum of the surface, the tubercular inflammation begins to spread in the epidural space, and the tubercular growth advances in the loose and vascular epidural tissue. In this way the dura mater is pressed upon the cord, partly by the tubercular granulations and partly by the tubercular abscess. Now reaction takes place in the dura, but a specific inflammation of this membrane does not yet occur. The process still remains a peri-pachymeningitis. It is only after the process has lasted for some time, that the peri-pachymenirgitis becomes a pachymeningitis; but even then the process is limited for a long time to the outer layers only of the dura mater. If the patient lives long enough the process finally passes through the dura, and then occurs the characteristics of a typical tubercular inflammation of the cord. Thus this specific tubercular myelitis never sets in until near the end of the disease to which the patient succumbs. The treatment should be by early and absolute rest to the affected part as the only thing to be depended upon to check the progress of the inflammation. In a few cases operation may be of service. In either case it is the aim of the treatment to cut short the progress of the tubercular proliferation before the cord itself has been invaded.

Abscesses in Pott's Disease.—Dr. Herbert L. Burrell, of Boston, sent a paper from which the following conclusions may be drawn: Efficient mechanical support of the spine is the prime factor in the treatment of caries of the spine associated with abscess. Under an expectant plan of treatment some abscesses will disappear. The indication for operative interference is a steady or rapid decline in the patient's general condition. The operation should consist of thorough evacuation of the abscess, and the establishment of drainage from as near the seat of the disease as practicable.

Treatment of Abscess of Pott's Disease.—Dr. W. R. Townsend, of New York, discussed the extreme views that have been advocated for and against operative interference in the abscesses of Pott's disease, and gave an analysis of three hundred and eighty consecutive cases. Seventy-five of these cases had abscesses, and the results of their treatment were given. Cases that were doing well were simply treated by braces; in some the abscess entirely disappeared. When the abscess was of a size to interfere with the application of a brace or with locomotion it was aspirated. In those cases where the abscess had become infected, free openings were made, thorough drainage established, and, where possible, diseased bone scraped. The results were good, despite the fact that nearly all the cases at the time of operation, or at some subsequent dressing, became infected, though in all this infection was slight.

On the Evacuation of Spinal Abscesses without Drainage.—Dr. G. A. Wright, of Manchester, England, sent a paper in which he said it would be hard to find a surgical problem more difficult to solve than that of the best method of treating abscess arising from tubercular disease of the spine. He especially mentioned Barker's method as the most scientific and practicable, but said that in referring to his notes he found that he had failed in most instances, but considered this due to the fact that the whole of the disease had not been removed. The ideal treatment would be the removal of the focus of the disease to which the abscess is due, together with the removal of the contents and wall of the abscess cavity. Unfortunately it was only in a minority of cases that this was practicable. Barker dealt with the abscess cavity by careful cleansing and removal from it of all caseous and tubercular material as far as possible, with an attempt at obliteration of the abscess cavity by immediate union of its walls.

The conclusions as to the treatment of spinal abscesses are: 1. The first essential is rest, in its surgical sense, to the spine. 2. When efficient rest has been provided an abscess should be left to itself for a period of not less than a month, unless it is increasing. 3. If the abscess increases, and is evidently going to open spontaneously, or if there is acute suppuration going on, the abscess should be dealt with by Barker's method, provided thorough asepsis can be practically assured. 4. An abscess that remains stationary for more than two months, or thereabouts, should be dealt with by Barker's method, provided rest has been afforded to the spine throughout the period. 5. Receding abscesses should be left alone. 6. Residual abscesses, if stationary or advancing, should be dealt with by Barker's method, and will nearly certainly be cured. 7. Refilling of an abscess or persistence of a sinus after evacuation should be dealt with by a repetition of the operation as soon as it is evident that repair will not take place, *i.e.*, usually in a month. 8. If there is a doubt about the real maintenance of asepsis, either from want of training on the part of the surgeon or his assistants, nurses, friends, etc., the abscess either should be left alone or dealt with by aspiration and injection of iodoform.

Bilateral Lumbar Abscess.—Dr. J. K. Young, of Philadelphia, related the history and presented the photographs of a very unusual case of recovery of a child, four years old, from severe bilateral lumbar abscess accompanying Pott's disease. He referred to the well recognized fact that abscesses in every region of the spine follow a pretty definite course and termination, the direction and exit of the pus being influenced by the seat of the lesion, and by the fasciæ and aponeuroses. He spoke of the course and exit of abscesses in the different regions of the spine, and did not believe sufficient attention had been given to the influence of the psoas and lumbar fasciæ in determining the direction of lumbar abscess, suggesting the division into internal and external lumbar abscesses.

The Benign Course of Abscesses in Pott's Disease under Efficient Mechanical Treatment.—Dr. N. M. Shaffer, of New York, made a few remarks upon this subject, not having prepared the paper announced.

The Aspirator in Orthopedic Practice.—Dr. Ap Morgan Vance, of Louisville, said that the use of the aspirator had been greatly neglected. It filled a place midway between the two extremes of leaving abscesses alone, and opening and draining them, and risking septic infection. He believed that three out of five of all spinal and hip abscesses can be cured by repeated aspirations, without an opening. Aspiration should be employed as early and as often as any fluid can be found. Firm compression is applied after each tapping, and the condition producing the abscess treated.

The Value of Mechanical Treatment in Old and Neglected Cases of Pott's Disease.—Dr. Henry Ling Taylor, of New York, said that the subject of mechanical

treatment in Pott's disease was twofold: first, to provide rest and protection to the spinal column, and proper hygiene for the patient, until the inflammatory process was arrested and repair was complete; secondly, so far as possible, to prevent or rectify deformity. Fortunately the same means, antero-posterior leverage support, might be adapted to both ends.

The course of the disease was often tedious and indefinite, healing slow. Complete bony anchylosis of the diseased vertebræ was both later and rarer than usually supposed, as indicated by more or less mobility through the kyphosis, often discoverable by careful testing in long standing and excessively deformed cases, and by the fact that in many such cases the deformity goes on increasing. Owing to imperfect treatment or other causes, symptoms and disability often persist for many years, coincidently with a gradual increase of deformity; or, after a considerable period of immunity, the original trouble may be lighted up by a strain or fall. The old and often apparently desperate cases, whether in children or adults, usually respond kindly to mechanical treatment, which should be employed with the same definite end in view as in more recent ones. The figure and carriage may sometimes be improved, and when this is impossible, increase may be prevented and the patient restored to health and usefulness. Abscesses and paralysis do not prevent a favorable prognosis in the large majority of cases. No patient should be denied the opportunity for relief on account of age, or long duration, or severity of the disease.

A Study of Atrophies.—Dr. Roswell Park, of Buffalo, said there is a great difference between arrest of growth and atrophy in a pathological signification, and yet one which clinicians as such cannot always or easily make. In 1837 Curling described a concentric and excentric atrophy of bone, also what he termed functional inertia, and the involvement of the central nervous system by which healing of injuries in paralytics is delayed. The writings of Bonnet, Verneuil, and others, and the discussions in the Paris Surgical Society, were considered at length.

The greatest importance was given to the researches of Ollier and his pupils. He established that the most common cause of hypertrophy of bone is irritation, and then studied the causes of their arrest of development and their atrophy. These causes he divided into those by which was produced destruction of tissue which concerns and favors their growth, and gradual failure in the evolution of such tissue. He carried out such a careful study of epiphysis, diaphysis, and conjugal cartilages, that he was able to show that it was not by a practical union of epiphysis to shaft that lesions of epiphyseal cartilages produce arrest of growth, but that the initial feature is arrest of proliferation of cartilage-cells. He also fully described the effect of fractures, of epiphyseal separations, of arthritis, and of anchylosis, in producing these tissue changes. Mutilations of bone almost always produce arrest of development, not alone in the bone operated upon or injured.

Diagnosis of Pott's Disease.—Dr. R. W. Lovett, of Boston, sent a paper in which he said that the diagnosis of Pott's disease does not rest upon the history of the case, and cannot be established by any subjective symptoms, however significant. The diagnosis as such must rest upon physical signs, and these are of two classes: those caused by muscular spasm and those caused by bony deformity. The symptoms caused by bony deformity occur late in the history of the disease, and it is very desirable that the symptoms caused by muscular spasm should be recognized, and the presence of the disease known before the occurrence of angular deformity.

Lateral deviation of the spine is almost a universal symptom in Pott's disease, and it is to be considered as a very suggestive symptom. High temperature is often of use in pointing to the probable presence of tubercular bone disease. The other diagnostic symptoms of Pott's disease were considered and a hasty *résumé* made of the differential diagnosis.

Open Incision on the Concave Surface in the Treatment of Inveterate Cases of Talipes Equinovarus.—Dr. B. E. McKenzie, of Toronto, sent a communication reporting nine cases operated upon since May, 1890. Four of the operations were performed upon girls from thirteen to fifteen years of age, and five upon boys from twelve to fourteen. The method of operating differs from that adopted by Phelps in making it consist of two operations, separated from each other by an interval of some weeks. In the first, the open incision on the inner side of the foot is made, cutting from a point a little in front of the internal malleolus and extending into the plantar surface, severing all tendons, ligaments and fascia that stand in the way of rectification of the varus. When any structure has been cut an effort is made to correct the deformity, so that as little cutting may be done as is actually demanded. The hand of the operator, as being more delicate for manipulation and sufficiently powerful, is used in correcting the deformity. Gypsum dressings are used to secure fixation in an over corrected position. When varus has been corrected and the operation wound healed, then the tendo Achilles is cut, and by manual force the equinus is corrected, and fixation bandages employed. By thus leaving the correction of the equinus to a later time, more power is gained in correcting the varus, which is really the difficult part of the work.

AMERICAN PHYSIOLOGICAL SOCIETY.

Second Day, Wednesday, September 23d.

Experimental Studies on Knee-jerk in Terminal Dementia.—The session was opened by the reading of a paper by Dr. William Noyes giving the results of his experiments as follows: *a.* During the cycles of depression and exaltation. *b.* During sleep.

He began his observations in 1890, and one of his greatest difficulties was to get a subject in whom the mental effects would be abolished. He succeeded in finding one who was completely demented, and at the same time perfectly tractable. He found that while in his ordinary condition of dementia that there was no increase of the knee-jerk on striking the ligamentum patella over that produced by a similar stroke on any normal individual, but during a period of extreme mental depression there was a marked decline in the knee-jerk, and when this period of depression began passing off there was a corresponding increase in the knee-jerk, until, when the subject had returned to his ordinary condition, the jerk was again normal in its character.

During Sleep.—The curves of the knee-jerks obtained from a subject during sleep showed several peculiarities. One was that the spinal cord could be aroused without disturbing the sleep of the subject or waking up the hemispheres. Any unusual noise in the room occurring at the time the blow was struck on the ligament, greatly increased the knee-jerk, which again declined as soon as the stimulation caused by the noise, such as the slamming of a door or a sharp rapping of a pencil upon a table, was withdrawn. The snoring of the subject indicated that he was in a profound sleep, and that the hemispheres were not awakened. Tracings showing the various effects on the knee-jerk caused by various noises were exhibited.

On one subject, who was in a state described as a semi-sleep, that is, he was apparently asleep but not snoring, the tracings varied greatly, and when he was aroused and talked with, the tracings of the jerk again became regular. Another point brought out was that when the stimulus was irregular the tracings of the knee-jerk were also irregular.

Knee-jerk Studied Simultaneously on both Legs.—Dr. J. W. Warren of Boston, Mass., read a paper describing

his experiments and their results in studying the knee, jerk on both legs simultaneously. His experiments were conducted in such a manner that one or both legs could be hit either together or an interval allowed to elapse between striking the right and left legs. The patient was placed in a chair, and a splint, with a hammer attached in such a manner that each and every blow was struck with the same force, was placed on his legs. The leg was well supported, so that no fatigue could be produced on the lower leg. By this arrangement the subject was unable to tell whether the blows were given on both legs at the same time or on either leg alternately.

An arrangement was also attached which recorded the kind of blow given, and whether one or both legs responded to the stimulus.

Results Obtained.—When the blows were given simultaneously on both legs they both responded. At first the jerk of the left leg was stronger than that of the right; but after the experiments were continued for a a time the jerk of the right leg increased until it almost reached that of the left.

In the midst of these double kicks, caused by double blows, a single blow on one leg was introduced and in the majority of instances the result of this single blow was a response from both legs. This was more constant in the left leg than in the right; after a number of such single blows were struck this difference between the right and left legs greatly diminished.

In another series of experiments, where at first a series of blows was struck on one leg, and then upon suddenly striking both legs simultaneously the right leg responded in only nine per cent. of the cases, and the left in sixteen per cent., thus showing a greater unwillingness on the part of the right leg in responding after changing.

Single Blows on One Leg after Giving Single Blows on the Other Leg.—At first, when one leg was given a series of single blows, and then a blow suddenly struck on the the other leg, the right leg responded in only three and one-half per cent. of all the cases and the left in seven and one-half per cent. This difference, however, decreased after a series of such experiments had been made on the same subjects.

Another very curious thing noted in a few cases was what might be called a double kick; that is, when a blow was struck on the right leg, at the time of striking the blow the left would respond with a backward kick followed by a forward kick, and in a very few cases the backward kick was even greater than the forward one.

Observations Mixed up with Sleep. — Dr. Warren found in his experiments that when a subject was drowsy or went to sleep, the knee-jerk was either diminished or disappeared entirely. During the sleep an effort was made to see if a moderate auditory stimulus would result in a kick—such as a slight rap given to a table—and in a large number of cases such a stimulus resulted in one or more kicks. However, there were a number of cases who were in a profound sleep, and on whom this stimulus produced absolutely no effect. On some of these cases where the stimulus failed to produce a response after a blow was given, he found that if he gave two blows without any stimulus, the leg responded, from which he concluded that the first blow roused the knee so that it was in a proper condition to respond to the second blow.

Dr. Donaldson, of Worcester, Mass., asked if the subjects on whom a series of blows were given on both legs, and then a single blow given on one leg, but which was responded to by a double kick, were ignorant of the character of the blow given.

Dr. Warren stated that the patient had no means of knowing what sort of a blow was given, either double or single. In reply to another question by Dr. Donaldson, Dr. Warren said that he thought it was a purely automatic action of the spinal cord.

Dr. Lombard, of Worcester, Mass., asked whether such a double kick from a single blow could not be produced by a jar transmitted from the tendon of the leg struck to the leg on the other side.

Dr. Warren said he could not see how it was possible for a jar to be transmitted without the lapse of a slight interval of time between the responses from both legs, and in his cases be found both legs responded simultaneously.

Dr. Bowditch, of Boston, Mass., stated that in his opinion the response from the other leg could be due only to a reflex action, and that it did not seem possible for a jar to be transmitted up through the entire body and down to the other knee, otherwise you would get a knee-jerk from a jar caused by a blow, even from the head.

THE AMERICAN PEDIATRIC SOCIETY.

(Continued from p. 367.)

Second Day, Wednesday, September 23d.

Congenital Heart Disease. — Dr. William Osler, of Baltimore, reported a case of congenital heart disease. In the absence of the author the paper was read on invitation, by Dr. W. T. Howard, Jr.

Drs. J. L. Smith and L. E. Holt, of New York, discussed the report.

Submembranous Treatment of Diphtheria.—Dr. A. Seibert, of New York, read a paper entitled, "Further Report on Submembranous Local Treatment in Pharyngeal Diphtheria, with Exhibition of Instruments." The paper was based on fifty cases in addition to those which had been published. He used for the injection about fifteen minims of the chlorine water of the United States Pharmacopœia. The fluid should be injected deep enough to reach below the pseudo-membrane. It should be remembered that the effect of the injection does not extend to membranous exudate located at a site distant from the point of injection, and that it is to be made into the submucous tissue.

Dr. H. Koplik, of New York, considered the paper as a perfect bacteriological report of therapeutics. We should remember that the disease, diphtheria, varies with different epidemics, and one treatment will be accordingly more or less successful.

Dr. W. P. Northrup, of New York, inquired as to the bacteriological conditions in diphtheria.

Dr. Koplik believed that the attempt of Dr. Seibert was proper as a bacteriological effort, though incomplete.

Dr. J. L. Smith, of New York, stated that the Klebs-Loeffler bacillus does not enter the vessels, but the product of it, the toxic agent which produces the systemic infection. If we injure the vessels we may allow of the entrance of the poison.

Dr. Holt had not had good results in the treatment of diphtheria by drugs. He thought diphtheria first a local, then a constitutional, disease, and the application of chlorine water he regarded as rational, if we take this view. He thought gargles and sprays useful, but he would not depend upon them for germicidal action.

Dr. J. H. Fruitnight, of New York, inquired as to details of treatment.

The President said that he was never sanguine in the treatment of diphtheria Where the diphtheritic exudate had been localized on the tonsils, he had had the best results in practice.

Dr. Putnam, of Boston, inquired about the extent of the membrane after injection and asked about the appearance of the throat so far as could be shown by œdema and congestion.

Dr. Seibert closed the discussion. He had found the Klebs-Loeffler bacillus in a large proportion of his cases. That alone would preclude the patients treated not having had diphtheria. He had seen extension of the membrane when he had not made his injections thorough enough. The œdema and congestion were always loosened and the mucous membrane made paler. He regarded diphtheria as a disease of the mucosa, and the in-

jections should be made into the sub-mucosa. The chlorine water has a local effect and does not enter the circulation. He had not often found it necessary to use a gag in the local treatment by chlorine water injection. The smaller the child the easier the treatment. If the first injection is thorough it will be unnecessary to repeat it. He would have it understood that he also used general medication.

Ulcerative Catarrhal Dysentery.—Dr. W. D. Booker, of Baltimore, read a paper on this subject, in which cultures were made of the bacteria in the stomach, different parts of intestine, and other abdominal organs, in one to three hours after death. The two species of bacteria found constantly in the intestine of milk-fed infants, were distributed in the intestine in this case more in correspondence with the healthy than the diarrhœal intestine. A species of bacteria was found in large number in the diseased part of the intestine and not in the healthy parts, which has not been found in the healthy or diarrhœal fæces. The distribution of bacteria in the mesenteric glands showed bacteria similar to the portion of intestines with which each gland was connected. Care was taken not to draw conclusions from a single case.

The Diagnosis of Pneumonia.—Dr. A. Jacobi, of New York, in continuation of his remarks on the diagnosis of pneumonia, made at the first session, said that enlargement of mediastinal glands may lead to difficulty in arriving at a conclusion. It might be necessary to delay expressing an opinion if such enlargement existed.

The following papers were read by title: "The Treatment of Laryngeal Diphtheria by Calomel Sublimations," by Dr. Dillon Brown, of New York. "Stricture of the Œsophagus Occurring in Children," by Dr. F. E. Waxham, of Chicago. "A Case of Pulmonary Abscess—Operation and Recovery," by Dr. F. Huber, of New York.

Progress of Medical Science.

The Presystolic Bruit — Professor Cantalamessa, of Bologna, says the presystolic *bruit*, which a Bolognese professor (Brugnoli) was one of the earliest to study (1859), is still by some regarded as pathognomonic of mitral stenosis. Flint, however, reported three cases of aortic insufficiency, in each of which a presystolic *bruit* was distinctly heard as well as the diastolic, but in which the mitral valves were found intact after death. His explanation was that the chordæ tendineæ of the mitral valve vibrated owing to increased tension during the auricular contraction, because the ventricle received blood both from the aorta and from the auricle. Keit thonght that the murmur was of aortic origin, due to the great difference of tension between the loaded ventricle and the empty aorta at the moment of beginning of systole. Bnt if so, Cantalamessa maintains, the *bruit* should be heard over the base of the heart, not the apex. De Renzi gave as the cause the meeting of the two currents of blood, one (abnormal) from the aorta, the other (normal) from the auricle. But this and Flint's hypothesis are, in Cantalamessa's opinion, open to the grave objection that if either were true a presystolic *bruit* ought to be very common in aortic insufficiency, which it is not. Nor is it heard in cases of great insufficiency, but only in rare cases, and then strictly localized over the apex. This suggested to Grocco the following theory: The regurgitation varying in amount and direction according to the degree and seat of the aortic lesion, if only one semilunar valve fail to act, the current backward will be oblique, and if directed posteriorly will cause the anterior bicuspid valve to become tense, and vibrate against the stream coming from the auricle, the brief auricular systole aiding. Further, if the backward current does not strike against the valvular cusp, it will still impinge against the ventricular wall, and in certain cases be reflected against the auricular current. After reference to the views of Dickinson, Constantin Paul, and Fenwick and Overend, Cantalamessa proceeds to examine why the first sound is strong in mitral stenosis, and weak, or even absent, in aortic regurgitation. The first sound is normally caused by (1) the heart muscle, (2) the atrio-ventricular valves, (3) the arterial distention. Which of these three will explain by its alteration the phenomena just mentioned? Certainly not the first, for in mitral stenosis the left ventricle is not hypertrophied; nor the last factor—namely, arterial distention—because in the same disease the pulse is small. There remains valvular tension as the cause. The more suddenly the valves pass from extreme relaxation to great tension, the more readily will a sound be produced. Now, in aortic insufficiency the refluent strain tends to make tense the valves gradually, so that in this final closure there is no abrupt change, and hence the first sound is weak or absent; but in mitral stenosis, owing to the negative pressure in the left ventricle, the valves are at one time extremely relaxed and then suddenly stretched, which causes a short and sharp first sound. As regards the presystolic *bruit*, Cantalamessa concludes that: (1) The *bruit* heard immediately before the first sound in mitral stenosis, in double mitral disease, and (occasionally) in aortic insufficiency, is really a presystolic *bruit;* (2) it is not pathognomonic of mitral stenosis; (3) its presence warrants the diagnosis of mitral stenosis only when a careful examination of other physical signs allows the exclusion of aortic insufficiency.—*British Medical Journal.*

Ehrlich's Test in Typhoid Fever.—This test, which has been known for a number of years, has till recently been regarded by many rather as a medical curiosity than as of diagnostic value. Dr. C. E. Simon, of the Johns Hopkins Hospital, has recently shown that by carefully following the precise directions for its use valuable information may be derived. The test consists of two solutions: 1. A saturated solution of sulphanilic acid in five per cent. hydrochloric acid. 2. A five per cent. solution of sodium nitrate. These are to be mixed, just before use, in the proportion of 40 c.c. of (1) to 1 c.c. of (2). If this mixture be added to urine from a case of typhoid fever, the further addition of ammonia will produce a play of colors varying from an eosine rose to a deep garnet red. The best method of applying the test is to take a few centimetres of urine in a test-tube, adding an equal quantity of the sulphanilic acid mixture, and shaking thoroughly; 1 c.c. of ammonia is then run carefully down the side of the tube. At the junction of the two liquids there will be observed a ring of the characteristic color, which is produced in scarcely any other disease than typhoid fever. Dr. Simon's conclusions may be thus summarized: 1. The reaction may be obtained in typhoid fever from the fifth to the twenty-second day of the disease. 2. Its absence from the fifth to the ninth day indicates a very mild attack, save in children, although this rule is not an absolute one. 3. As it occurs previous to the appearance of the rash, it is a very useful aid in the diagnosis of typhoid fever.—*Therapeutic Gazette.*

The Diagnostic Value of Laveran's Organisms.—Dr. Townlin, of Baltimore, has had considerable clinical experience in malarial fevers. Regarding the importance of the organisms of Laveran in recognizing obscure cases, he has arrived at the following conclusions: 1. There are cases in which, from history, symptoms, and signs, we cannot differentiate between malarial fever and certain other diseases. 2. In examining the blood of these cases for the presence or absence of Laveran's organisms, we have a means of diagnosis at once accurate, practical, and practicable. 3. Those cases are rare in which the organisms, though present, cannot be found, and they do not exist at all if the examinations are careful and the examiner has had experience.—*Medical News*, September 19, 1891.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, September 26, 1891.

HOSPITAL REPORTS.

We have recently reviewed in another column a volume of hospital reports issued from the Blockley Institution in Philadelphia, which, in a medical way, corresponds to Bellevue in New York, though with, we believe, a considerably larger capacity. It is a creditable volume in every respect. As we have looked over its pages and have seen how much valuable clinical information has thus been recorded in a concrete form, we have been forcibly reminded of the poverty in this department of medical literature in our country at large, and in our own city in particular. The glory of such English institutions as Guy's, St. Thomas's, the London, and other hospitals, comes largely from their well-digested reports, which appear regularly and have a recognized place and standing in general medical literature.

It is not at all creditable to us here in New York that such a state of affairs exists. We have the institutions, some of them of a good age. Nearly all of them are fairly provided for in a material way. We have the men who are doing good work in them. We have a vast amount of clinical material—so vast, in fact, that only a small proportion of it is utilized as it might be. In fact, we have everything except—satisfactory reports.

Why is it? We can think of several reasons. And the first one is the mistaken idea which hospital managers have of the proper nature of a hospital report. In the average report as now issued too much attention is given to the domestic side, and too little to the professional side, of the institution. If an institution makes no appeal to the public for funds, it is under no obligation to give a detailed account of its expenditures. If it does appeal to the public for money, such financial statements as the public is entitled to could be published in the newspapers and reach a much larger number of people than does the present system of annual reports, and would also cost much less. Too much space is taken up with details which are of no earthly use to any but those who actually have the direction of the institution and buy its supplies. No one cares how many bars of soap have been used in the laundry or how many bags of oats the ambulance horse has eaten. The name of the institution vouches for cleanliness of linen and sound horseflesh. If the money spent in the publication of these useless details could be diverted toward elaborating the medical side of the report, great good might be done.

In regard to the latter side, a different principle should prevail in the preparation of the reports. A proper report has two parts, first, tabulation, as preparatory to the second, analysis. We now stop short at the first. Under the heading of, say, typhoid fever, we read: "Males—females, total; recovered—died—remaining in hospital." We submit that such information is not very valuable. It costs money to publish reports, we know, but if the money is properly expended, the proper kind of reports can be published at very little, if any, greater expense than the present faulty ones.

This reform must come from the medical officers of the hospitals. Right here we must bring an indictment against some hospital attendants. There has been a great gain in some respects in the adoption of the so-called "continuous-service" plan. But in others there has been a loss. There is little doubt, it seems to us, that the hospitals are not as widely diffusing, under the present system, the general benefits arising from the work they do as was formerly the case when there were more attendants. The benefits are now confined to a few. The latter, in virtue of the positions which they hold, have a certain duty to the profession at large. They, and they alone, can furnish the necessary stimulus to proper editorial work on the reports, and they should be willing to do so.

We believe that this work can only be done by the appointment of a medical officer, to be known as the editor. He should receive a proper compensation. The work must be under the direction of one man who has time for it. What is everyone's work is done by no one. He should be allowed to indicate the lines along which histories should be taken by the house staff. As it is now, Dr. A—— takes very good histories for six months without any suggestions from anyone; but his successor, Dr. B——, in whom the literary talent has no development, makes wretched work of the task. No one fails to appreciate this unevenness who tries to look over old hospital reports in manuscript. There is such a variation in the ways in which they have been taken that it is almost impossible to properly analyze the facts they contain.

We are glad to notice that the reports of the last two years from one or two of our private institutions—those supported by endowments—show an advance along the lines indicated. Therapeutics begin to receive attention. Unusual cases are given with some detail. Tabulation is made subordinate to analysis. We hope the reform thus begun will continue and spread to other institutions, and that the reproach under which New York now labors in this direction will soon have no cause for existence.

BICYCLING AS AN EXERCISE.

The enormous popularity of the bicycle since the "Safety" type has been introduced, makes the question of its use an important hygienic and medical problem. A writer in the New York *Times* quotes the following comment of a physician:

"I must put my boy at a gymnasium to counteract the effect of his Safety, which his mother persuaded me against my better judgment to buy for him. I am strongly opposed to bicycles for growing lads. It develops a little

leg and arm muscle which any ball playing, running boy gets without it, and it also develops very frequently round shoulders and contracted chest. At least it does in my son, and he was a straight lad with a good breadth of chest before he began to ride."

Against this opinion, however, must be set one quite different, heard at the same time. "It all depends on the way a boy begins, whether the exercise is beneficial or not," was the comment of a second father; "he should not be allowed to teach himself, but be sent to some instructor, from whom three or four lessons will suffice. He will be taught to mount properly, sit well, and ride in an erect position. It is as important as to be taught how to ride a horse. Any boy or man can stick on a horse, but there is every difference in the manner in which boys and men ride the animal. I am convinced that bicycling is a good exercise for a growing boy, with plenty of pleasurable profit in it, if it is properly done"

We recall the opinion of some English writers on this subject, who asserted that a urethral stricture might be produced in boys by its excessive use. Such a danger is probably purely fanciful in connection with modern bicycles and properly constructed seats; for the weight of the body does not come upon the perineum at all. On the whole, we believe that medical opinion inclines to favor the bicycle as a means of exercise, as containing very few elements of harm or danger. It can only be said that excessive addiction to the machine, especially the indulging in racing, and faulty methods of holding the body, will do harm, particularly to growing boys.

THE THERAPEUTIC USE OF EXTRACTS OF ANIMAL TISSUES.

The persistence and ingenuity shown by Dr. Brown-Séquard in his study of the physiological effects of the juices obtained from the testicles and other glands of the bodies compels attention and interest. It seems to have been quite well proved that the injections of testicular juice have no such "dynamogenic" power as was at first alleged. That this and other secretions, however, have no physiological influence is certainly improbable, and, according to Brown-Séquard and his co-workers, is positively untrue. In an article on "The Action of Liquid Extracts Obtained from Different Organs," by Drs. Brown-Séquard and D'Arsonval (*Archives de Physiologie*, 1891, No. 3), evidence of this belief is presented, and the technique of preparing and using the extracts is described. These authors assert that each gland of the body has two functions, one, that of secreting a substance from the blood, the other, that of supplying to the blood some needed constituent. It is this latter substance which it is proposed to obtain and use therapeutically. It is stated that the secretions themselves contain some of the dynamogenic or other substance required by the organism. In illustration, the extraordinary fact is cited (p. 492) of a young physician who injected hypodermically some of his own sperm into his invalid wife's tissues. Her strength improved, and after four injections she was well. This is truly an extraordinary method of fulfilling the conjugal relations, but they do rude things in France.

The authors quoted give a number of illustrations to show that injections of the fluid of certain glands relieves symptoms caused by extirpating those glands. Thus, in the case of a dog suffering from the effects of the total removal of the thyroid, the symptoms were relieved by the injection of juice of the thyroid. A total extirpation of the pancreas causes, it is said, diabetes, but if a small part of the gland is left this accident does not occur; and this is thought to be due to the so-called external or extrinsic action of the gland upon the blood.

A wide therapeutic field opens before the scientific imagination if the views suggested above are true. Thus in myxœdema, injections of the thyroid juice should be used; in Addison's disease, the juice of the supra-renal capsules; in diabetes, the pancreatic juice; in leucocythæmia, the juice of the thyroid glands, spleen, and medulla of bones; in muscular weakness, the muscle juice.

The injection of these juices, however, unfiltered and unsterilized, is not free from danger, the testicular and ovarian juices alone excepted. Other juices are liable to cause death from septicæmia.

In order to render injections aseptic and harmless, our authors submit the fluid to a pressure of CO_2 of 40 atmospheres, and then pass it through a specially constructed filter. Bacteriological tests by MM. Straus and Gamaleia show that the fluid now contains no microorganisms, and experimental tests show that its use causes no accidents.

The juices are extracted with glycerine, and after they have been treated so as to be made innocuous, are kept in sterilized flasks. According to our authors, over 15,000 injections have been made by various physicians in Paris. With such a large experience it is unfortunate that no reports of definite therapeutical results are yet furnished. We trust that these will come later.

WHERE MEDICAL PRACTICE IS EASY.

Timid souls who dislike examinations, and ignorant ones who know they could not pass one, are finding their field for medical practice gradually becoming more and more restricted. Some of the conservative old New England States are, however, still open to them, and in Connecticut especially they can roam at will and hurl their death-dealing shafts without restraint, as witness the following letter, published in the Board of Health *Bulletin* of that State. The letter was sent in reply to an inquiry from a physician concerning the restrictions on practice there existing. "Sir: Anybody can practise medicine in Connecticut. You do not need to register; you do not need a medical diploma; you do not need to know the difference between opium and peppermint; you do not, indeed, need to know anything. You can simply come and live here, and begin to practise. The laws of Connecticut will sustain you in collecting your fees for professional services, if you render any which you choose to call such. But if you undertake to carry me or my trunk to the depot for pay, you must get a license. If you peddle matches or peanuts, you must get a license. If you collect the swill from your neighbors, to feed your pigs, you must get a license. If you want to empty your cesspool, you must get a license. But you can practise medicine in Connecticut without a license."

As this letter witnesseth, the reputable practitioners in

the conservative old commonwealth to the east of us are growing restless. We would therefore advise the lazy one who is casting about for an easy berth to bestir himself, for many sessions of the legislature will not pass ere our neighbor falls into line with the other States that have some regard for the lives of their citizens, and shuts the door on medical free lances.

LONDON DOCTORS ON THE DRINK QUESTION.

The London daily papers have a habit of inviting the public to share in certain discussions in their columns on topics of current interest. It seems to be becoming a custom for eminent medical men to take part in these discussions. While we cannot see any particular reason why a doctor should not contribute his share to the diffusion of knowledge as well as a lawyer or clergyman, still the custom strikes Americans as being a rather odd one, particularly for so conservative a country as England. The latest bit of wrangling has been over the old, old topic of alcoholic liquors; the especial interest this time has been over the radical and defiant attitude of "the celebrated alienist of Hanover Square, Dr. W. [J.?] Mortimer Granville." Dr. Granville, we are told, comes out strongly in favor of rum. He says, according to the *Sun*, apropos of Sir Wilfred Lawson's quotation from Lord Althorp, "the cause of drunkenness is drinking," that "drunkenness is in no other sense the consequence of drinking than the destruction of a house by fire is the consequence of having a cooking range on the premises," and goes on to say: "It is not to engage in the puerile play of words with Sir Wilfred Lawson and the advocates of what I believe to be one of the weakest and most mischievous crazes of the nineteenth century—I mean teetotalism—that I ask you to give me space in your columns, but because I think the time has arrived when it is desirable that someone who has strong views on the subject of what it is the fashion of the day to denounce as 'drinking,' should speak out honestly. I have never shared the opinions of the many in my profession on the drink question, and I have not intentionally veiled my view of the issue so repeatedly raised and so hotly discussed; but the moment appears opportune for plain speaking, and I trust this may be permitted not only to those who seek to convince the public mind that alcohol in all its forms is needless to the health, and of only questionable value to the sick, but to those who hold that it is far better that the healthy should be moderate drinkers than abstainers, and that the great value of alcohol in the treatment, and I will go further and say, in the prevention, of disease, should be clearly recognized." Further than this, Dr. Granville says that he honestly believes that the propagation of teetotal doctrines is exercising a destructive influence on the moral, mental, and physical health of the people, and that those who have rational views on the matter are doing a great wrong in giving way, step by step, before the aggressive policy of the teetotal advocates.

For the utterance of these views Dr. Granville gets pummelled vigorously by some of his esteemed confrères. And this is no more than right. For, while it is not yet precisely shown that alcohol in moderation does harm to the majority of people, it has equally not been shown that a total withdrawal of it would be injurious. Therefore Dr. Granville is only sensationally promulgating an opinion that may or may not be true. It is not a demonstrated fact.

THE THERAPEUTICS OF THE SENILE HEART.

Dr. George W. Balfour has published, in the *Edinburgh Medical and Surgical Journal*, a useful series of papers on the therapeutics of the senile heart.

As in old age it is the heart and vessels which oftenest give trouble and warn the patient that his declining years have come, the treatment of these conditions naturally excites interest.

The senile heart is essentially, says Balfour, a heart in which the main trouble is malnutrition. It is not, however, a fatty heart, this being a very rare condition, and one "impossible to recognize."

The first symptoms of approaching senility of the heart are irritability and a sensation of uneasiness in the cardiac region, sometimes amounting to pain. Along with this there may be fits of palpitation, in the form of rapid but not usually forcible action, which come on after exertion, such as running rather quickly upstairs, upon any excitement or sudden emotion, or during the night from reflex causes, mostly of gastric origin; or there may be fits of *tremor cordis* coming on suddenly, without warning and apparently without cause. The rhythm of the pulse is occasionally and temporarily irregular in force and frequency; or it may simply intermit, drop a beat at irregular intervals; or this intermission or dropping of a beat may occur at regular intervals of longer or shorter duration, and this regular intermission may either be constant, or only occur occasionally at irregular intervals, and mostly as the result of emotion or of gastric disturbance.

These phenomena are always indicative of cardiac debility, which, left to itself, sooner or later leads to dilatation of the heart, as well as the other serious symptoms which we find associated with senile degeneration of that organ. After a time attacks of cardiac failure or of angina may occur; but this is not always the case. Many patients suffer for years from the *tremor cordis* and other symptoms, without any more serious trouble supervening. The pulse may be small, soft, and compressible, with a low blood tension. In these cases there is more often anæmia of some form. If the pulse is hard and tense, then we may suspect a gouty or renal complication, or both. Sometimes the arteries are plainly hard from atheroma, and yet the blood-tension is low; and here we must suspect a feeble and dilated heart.

When the blood-pressure is low, carefully graduated exercise is especially indicated.

A great deal of importance is attached by Dr. Balfour to the diet, especially in cases complicated with obesity. His main rule, however, is temperance in food and drink; another important point is that the meals should be five hours apart, and that the heavy meal should be in the middle of the day. Very little fluid should be taken at the meals, and alcohol is much better not taken at all. Tobacco also does harm, as a rule.

Among drugs stress is laid upon digitalis, given in small doses in the form of the tincture. Strychnine, arsenic,

the nitrates, and in cases of high tension the iodide and bicarbonate of potassium, are recommended. For constipation and flatulence he advises the old compound galbanum pill.

News of the Week.

The Journal of Comparative Neurology, edited by C. L. Herrick, and published quarterly at Cincinnati, is a most creditable contribution to scientific periodical literature, and we cordially welcome it among our exchanges.

Hydrochloric Acid in Diphtheria.—Starting from the fact established by Roux and Yersin (*Bulletin Medical*, 1889), that the virulence of diphtherial toxins can be considerably diminished by slight acidulation of the bacterial products—especially with some mineral acid—Dr. S. H. Kraszewski, of Ivyë, resolved (*Gazeta Lekarska*, No. 28, 1891, p. 555) to try hydrochloric acid in six typical cases of croup in children, aged from six months to three years, and in five cases of faucial diphtheria in two children and three adults. The following formula was used: ℞. Liq. ferri perchloridi, *Ph. Ross.* (that is, equal parts of the iron salt and distilled water), 4 grammes; acidi hydrochlorici, 1.0 gm.; aq. destillatæ, 200.0 gm. M. D.S: A teaspoonful every fifteen minutes for one hour; then every thirty minutes for three or four hours; later on every hour. In faucial diphtheria the remedy was applied locally as follows: ℞. Liq. ferri perchloridi, *Ph. Ross.*, 8.0 gm.; acidi hydrochlorici, 1.0 gm.; aq. destill., 30.0 gm. M. D.S: To be painted over the affected area with cotton-wool every two hours, a fresh piece being used on each occasion. The treatment lasted from two to five days, the only adjuvants employed being frequent gargling with a four per cent. solution of boracic acid in faucial diphtheria, and the internal administration of a 1.5 per cent. solution of sulphate of copper in croup (as an emetic when symptoms of laryngeal obstruction were present). Every one of the patients made an excellent recovery. In four out of five faucial cases the diphtheritic deposits vanished completely and permanently in from twenty-four to forty-eight hours, the throat becoming normal within three or four days. The fifth patient recovered in a week. The laryngeal cases (of which two had been apparently hopeless) were cured in from three to five days. In none were any unpleasant accessory effects observed.

A Heavy Dose.—This is the order which a little girl brought into a Lewiston druggist's store the other day. It was written on a dirty piece of note-paper, as follows: "Mister druggist: Please send ipecac enough to throw up a four-year-old girl."

Organization of the State Board of Medical Examiners.—The Board announces that it organized, September 1, 1891, with Dr. William C. Wey as President and Dr. M. J. Lewi, of Albany, as Secretary. The following assignments for examination purposes were made: Physiology and Hygiene, William C. Wey; Surgery, George Ryerson Fowler; Obstetrics, William Warren Potter; Anatomy, William S. Ely; Chemistry and Materia Medica, Maurice J. Lewi; Pathology and Diagnosis, J. P. Creveling; Theory and Practice and Therapeutics, Eugene Beach.

A committee to scrutinize all questions submitted by the twenty-one examiners composing the three boards, consisting of two representatives from each board, was agreed upon, and from our body Drs. Fowler and Lewi were appointed. This same committee of six was furthermore charged with the duty of preparing a syllabus. The method of examination agreed upon will be as follows: Each of the twenty-one examiners will transmit to the Secretary of the University of the State of New York, on or before September 15, 1891, by registered letter, at least sixty questions on the topic to which each may have been assigned. At some date thereafter, on the call of the Secretary of the University, the committee of six above referred to, who are known as the Questions Committee, will convene in a room set apart by the Regents and supervise the preparation of all examination papers to be made up from the questions submitted, having the privilege of omitting such questions as may seem impracticable, unfair, or otherwise unsuitable—however they will have no power to add or substitute questions. This review of questions is vested in the committee on all subjects other than therapeutics, practice, and materia medica, in which branches the law states that "the questions shall be in harmony with the tenets of the school selected by the candidate"—accordingly the two representatives from each board will have the sole revision of the questions submitted by the examiners from their board on these topics.

The conference of the three boards agreed upon the following recommendations, to be submitted to the State Board of Regents, which body will undoubtedly ratify the action of the Board of Examiners: 1. A medical syllabus to be prepared (covering all subjects in which examinations are to be held) under the direction and supervision of a committee of six, to consist of two members appointed from each board. 2. A committee on questions, composed of six members, two to be appointed from and by each board, whose duty it shall be, on the call of the Secretary of the University of the State of New York, to convene at Albany and revise all questions submitted by the individual examiners under section five (5) of the law. 3. Each question paper on the seven topics shall consist of fifteen questions, of which the candidate shall cancel five and be marked on his answers to the remaining ten. 4. One hundred points shall be the standard, and each candidate must secure 75 points in every branch before his or her name shall be recommended to the Regents as a proper person to be licensed to practise medicine in this State. 5. Four examinations shall be held during the coming year in New York, Albany, Syracuse, and Buffalo, the dates of which may be fixed at the discretion of the Board of Regents. 6. All examinations shall be conducted in the English language. 7. Examinations for medical license shall be conducted on all subjects at one examination consisting of the requisite number of sessions. 8. No conference of the Board of Medical Examiners shall be held excepting on request of a joint call by a majority of the members of at least two of said boards, as certified to the Secretary of the University by the proper officers. 9. If, in the opinion of the Board of Regents, it becomes necessary or advisable, additional examinations shall be held as occasion may arise. 10. At least sixty questions by each examiner in his depart-

ment shall be sent by registered letter to the Secretary of the University, on or before September 15, 1891.

International Congress of Hygiene and Demography.—The next meeting of this Congress will be held in Buda-Pesth in the summer of 1894.

Arthritis of Obesity.—At the fourth general meeting of Russian Medical Men, Professor Vasily I. Kiizmin, of Moscow, read a paper on certain forms of chronic inflammations of joints, dwelling especially on "arthritis of obesity," and advocating the following general propositions: 1. In stout subjects there fairly frequently occurs a peculiar variety of chronic arthritis which mainly attacks the knee articulations, but may also develop in the hip and shoulder joints. 2. Apart from accidental causes such as rheumatism, cold, etc., the most important part in the causation of the affection is played by a lowered systemic tissue metabolism and—in cases of a rapidly developing obesity—by an over-burdening of the joints by the bodily weight. 3. In arthritis affecting the lower limbs, another important factor favoring its development is constituted by disturbed circulation (congestion) in the extremities. 4. The best treatment of the joint disease consists in measures for decreasing obesity (and with it the bodily weight, etc.)—hot baths, douches, electricity, massage, and alkaline mineral waters.

Some of the Amenities of Medical Journalism.—A contemporary of the Southwest, whose language is a little too violent at times to render him wholly and heartily esteemed, refers in the following affectionate terms to another medical editor to the north of him: "—— is a notorious liar. He is not only a liar, but a dirty lap-eared cur. He subsists on filth; filth is his only food. He grovels in putrescence; he delights to root up, with his filthy beak, the reeking cesspools of falsehood and calumny. He is a base ingrate; a dirty whelp, wholly destitute of honor and a disgrace to his *alma mater*. For years this fellow has attempted to do us injustice and injury. For four years we allowed his dirty insinuations to go unnoticed, but now and henceforward we propose to give the dirty little rascal successive lambastings he will not soon recover from. By some hook, crook, or turn, he has succeeded in hooking himself onto a medical college as a 'p-r o-f-e-s-s-o-r.' Ye gods and little fishes. A professor? If such ignorant bombastic boors are allowed to teach medicine, the question of higher medical education should be no longer discussed." And much more of the same kind.

The Population of the Sandwich Islands.—The preliminary returns of the census of Honolulu and the Hawaiian Islands, which was taken on December 28, 1890, were made public by the Secretary of the Board of Education recently. The total population of all the islands of the group is 89,990, of which number 34,436 are natives, 15,301 Chinese, 12,360 Japanese, 8,602 Portuguese, 1,928 Americans, 1,344 British, and 1,034 Germans. The population of Honolulu is 22,907, divided into 13,998 males and 8,909 females.

The Medical Society of Virginia will hold its twenty second annual meeting in Lynchburg on Tuesday, October 6th, and the two or three following days. The following programme is announced: Report on Anatomy and Physiology, by Dr. Paul B. Barringer, of University of Virginia; Report on Chemistry, Pharmacy, Materia Medica, and Therapeutics, by Dr. Benjamin Harrison, of Richmond; "The Place of the Turkish Bath in the Treatment of Disease," by Dr. Charles H. Shepard, of Brooklyn, N. Y.; "Pharmacy and Its Practical Relation to the Profession," by Dr. S. J. Baker, of Bedford City; Report on Obstetrics and Diseases of Women and Children, by Dr. Herbert M. Nash, of Norfolk; "Puerperal Eclampsia—Its Etiology and Treatment," by Dr. J. T. Graham, of Wytheville; "Etiology and Pathology of Puerperal Inflammations, Illustrated with Specimens," by Dr. Thomas A. Ashby, of Baltimore, Md.; "Retrodisplacements of the Uterus," by Dr. H. P. C. Wilson, of Baltimore, Md.; "Recognition of Operative Cases in Gynecology by the General Practitioner," by Dr. Joseph Hoffman, of Philadelphia, Pa.; "Remarks on Salpingitis and Peritonitis—the Result of Gonorrhœal Infection," by Dr George Tucker Harrison, of New York; Report on Practice of Medicine, by Dr. Lewis E. Harvie, of Danville; "Importance of the Microscope to the General Practitioner as an Aid to Diagnosis and Correct Medical Treatment, with some Demonstrations in Bacteriology," by Dr. James E. Reeves, of Chattanooga, Tenn.; "Hæmorrhoids and Their Treatment," by Dr. J. N. Upshur, of Richmond; "Symptomatology and Treatment of the Chronic Forms of Nephritis," by Dr. William C. Dabney, of University of Virginia; Report on Surgery, by Dr. Thomas M. Bowyer, of Sioux Falls, S. Dak.; "Present Aspect of Cerebral Surgery," by Dr. Landon Carter Gray, of New York; "Perineal Operations," by Dr. Joseph Price, of Philadelphia, Pa.; "Concussion of the Lungs," by Dr. B. A. Watson, of Jersey City, N. J.; "A Successful Myomectomy for Parasitic Tumor," by Dr. I. S. Stone, of Washington, D. C.; "A Plea for Closer Study of the Principles of Surgery by the General Practitioner," by Dr. George Benjamin Johnston, of Richmond; A paper by Dr. A. M. Phelps, of New York; "Treatment of Goitre by Electrolysis," by Dr. Charles M. Shields, of Richmond; Reports on Ophthalmology, Otology, and Laryngology, by Dr. J. Herbert Claiborne, Jr., of New York, and Dr. John Dunn, of Richmond; "Ophthalmology in Ancient Egypt," by Dr. W. H. Baker, of Lynchburg; "Some Personal Observations on Cataract Operations," by Dr. A. W. Calhoun, of Atlanta, Ga.; "Mistaken Impressions about so-called Nasal Catarrh," by Dr. Joseph A. White, of Richmond; "Some Suggestions about Cataract Operations," by Dr. Joseph A. White, of Richmond; Report on Neurology and Psychology, by Dr. William F. Drewry, of Petersburg; "Hereditary Chorea," by Dr. Wharton Sinkler, of Philadelphia, Pa.; Report on Hygiene and Public Health, by Dr. W. T. Oppenhimer, of Richmond; "The Drink Problem from a Medical Point of View," by Dr. T. D. Crothers, of Hartford, Conn.; "The Drink Problem from a Medical Point of View," by Dr. Frederick Horner, of Marshall; "What is to be Done with our Criminal Lunatics?" by Dr. J. T. Graham, of Wytheville.

Nervous Diseases in Japan.—Dr. Wallace Taylor, in his Report of the Osaka Medical Work of the Japan Medical Mission, says that neuralgia is very frequent in Japan. Multiple neuritis is also common, chiefly in the endemic form of *kakke*. Polio-myelitis, especially the

infantile form (infantile paralysis) is frequently met with. Excepting paralysis from *kakke* it is the most frequent form of paralysis seen in Japan. But lateral sclerosis (primary spastic paraplegia) is not often seen in clinics, nor are such patients seen *stilting* along on the streets in Japan, while posterior sclerosis (locomotor ataxy) is almost unknown. We have yet to see the first case in Japan. It is reported that such cases are occasionally seen in Tokio. Meningitis is frequent in hot weather.

American Students in Berlin.—The number of American students in Berlin this summer is unusually great. At the University alone the number is 208 out of a total of 5,547. Many others are attending private clinics, studying Koch's methods, learning the German language, or pursuing studies in art and music. Most of the Americans at the University are graduates of American colleges, Harvard, Yale, Princeton, and Johns Hopkins being the most largely represented. There are many graduates also of American medical and theological schools. More Americans are attending the medical lectures than any other courses, Koch, Virchow, and Bergmann especially attracting them.

The Point of View.—The following questions in Materia Medica and Therapeutics were asked by the New Jersey State Medical Board at its April examination :

Materia Medica and Therapeutics.—1. What is dialyzed iron, and how is it prepared? 2. What is cantharides? Its uses and doses when internally administered? 3. What is chloroform? Its specific gravity, uses, and doses? 4. Give the formula and mode of making camphorated tincture of opium. 5. Give the formula of the compound cathartic pill of the United States Pharmacopœia. 6. Give average internal dose of each of—1, atropia; 2, morphine; 3, strychnia, for a child four years of age. 7. How is antifebrin prepared? What are its physiological effects, uses, and doses? 8. Describe infusion, decoction, maceration, and digestion. 9. Give five irritant poisons and the antidotes of each. 10. Write a prescription containing nitro-glycerine, and give the symptoms to be relieved.

Homœopathic Materia Medica and Therapeutics.—1. Explain the difference that exists between the primary and secondary action of a medicine, and give an example. 2. Name the most important remedies, with their doses, for dysentery in an adult. 3. Differentiate the brain symptoms of cuprum aceticum and stramonium. 4. Give the thoracic symptoms of bryonia alba. 5. Give the enteric symptoms of colocynthis. 6. Describe the characteristic inflammation of belladonna. 7. Give the urinary symptoms of cannabis sativa. 8. Name the most valuable remedies in diphtheria—the simple and malignant forms. 9. Describe a disease in which hydrastis canadensis is the indicated remedy. 10. Give the skin symptoms of antimonium crudem.

The Danger of Administering an Anæsthetic to a Woman, Unless in the Presence of a Third Party, is well illustrated in the following case which we find reported in the *Sei-I-Kwain Medical Journal*: "A woman, named Kin Mihashi, aged twenty, having been suffered from the uterine disease, consulted of a physician at Yokohama, who administered anæsthetic. While under the influence of the drug, as she stated that the doctor conducted the immoral action, and appeared before the court yesterday. It is advisable for a young physician not to give anæsthetic without the presence of another professional man, especially in case of female, as the effect of the drug often gives such a peculiar strained sensation to the patient, as some one insulted her immorally while under the influence of the drug."

Death in the Jam Pot.—A correspondent of the *British Medical Journal*, in calling the attention to a danger that attends the use of glass jars for holding a jam, writes: "Twice within the last two months have my children found pieces of glass in their months, and fortunately got it out again; one piece was half an inch long and very sharp. If this has happened twice in so short a time to me, how often must it occur to others, and how often must the children swallow a piece without knowing it? It makes one look back to the obscure case of enteritis one has met with, which could not be accounted for as to the cause. The jams my children had were from different makers, so the accident must not be uncommon."

What Did Shakespeare Die of?—There is a tradition of very respectable antiquity that he died of a fever contracted through going on a drinking bout with Ben Jonson and other boon companions. Mr. J. F. Nisbet, in his new work, "The Insanity of Genius," discusses the question from an entirely new point of view, that of pathology. In the author's opinion, Shakespeare died of paralysis, or some disease akin to paralysis. The signature to the will, he holds, affords strong presumption of this, but he has also other facts to adduce in support of this theory. In 1657, Dr. Hall's medical cure-book was published by James Cooke, "A practitioner in physick and chirurgery." Dr. Hall, as is well known, was Shakespeare's son-in-law, and his book proves beyond doubt that nervous disease existed in Shakespeare's family, a fact which Mr. Nisbet considers accounts for the short average duration of the lives of its members, and the speedy extinction of the line of Shakespeare's direct descendants.—*Medical Times.*

Catelectrism is a name proposed by a correspondent of the *Sun* for execution by electricity. He says that it is etymologically correct, terse, clear, precise, and one that can be readily adopted by any language. The verb would be catelectrize, and the correct accessory forms catelectrist, catelectric, etc.

The Electric Fan in the Reduction of High Temperature.—An editorial writer in the Texas *Health Journal* suggests that the electric fan may be pressed into service in the lowering of high temperature in fever. He says that he does not know of an actual test being made of the power of the electric fan, or wheel, in reducing the temperature in fevers, but its great force in cooling the surface of the body leads him to believe that it will act very similar to the cold bath, as used in many forms of fever. It would seem to be a simple matter to determine whether or not the electric fan will lower high temperature. But whether it will or not, it certainly would be an excellent sanitary measure in typhoid and other slow cases of fever, causing a constant renewal of the atmosphere, driving out the contaminated air of the sick-room, and forcing in fresh air to take its

place. The fan would also blow away all mosquitoes and flies from the neighborhood of the patient's bed.

A Case of Trichinosis from eating raw ham occurred in Hoboken last week. The patient was a young woman of nineteen.

Vacancies for Medical Men in the State Asylums.—It is stated that there are about sixty physicians, including nine women, employed in the ten insane asylums, now called State hospitals. Since these positions were thrown open to competition, in November last, two competitive examinations have been held. The number of competitors in these examinations has been small, and the eligible appointment list resulting has been exhausted. The salaries paid junior assistant physicians range from $800 to $1,600 per annum, including board. Candidates must be residents of the State, and have had one year's experience in a hospital, or three years' experience in the general practice of medicine. Promotions are made without examination between the grades of junior and first assistant physicians. The absence of applicants for these positions shows, we think, not that there are not plenty of young medical men who want such places, but rather that the qualification of a year's work in a hospital is much rarer than it should be.

Medical Students in Europe.—The number of young men who go in for university training increases yearly in every country of Europe, though the relative increase is notably affected by the length of the course of studies imposed. The tendency is less marked in France and Germany, on account probably of the preponderance of the military spirit and the need for a supply of officers. Leaving on one side the students of theology, and taking 100,000 inhabitants as a standard of comparison, we find 82.3 students in Belgium, 76.6 in Norway, 57.3 in Sweden, 55.9 in Austria, 51 3 in Italy, 50.4 in Switzerland, 48.1 in Germany, 45.4 in Holland, 42.6 in France, and—least as well as last—9.9 in Russia. Taking the same basis of comparison, there are 14.4 medical students in France and Germany, 23.8 in Austria, 26.7 in Holland, 24.2 in Belgium, and 20.6 in Italy. The increase, compared with the proportion during the seventeenth century, varies from 148 per cent. in Germany to 214 per cent. in Norway.—*Medical Press.*

A Blow at Vegetarianism.—According to Raymond, Gubler, and E. Monin, a vegetable diet tends to produce atheroma of the arteries.

A Professional Faster named Jacques has broken the world's record and fasted for fifty days, taking only water and a certain herbal powder. His weight diminished from one hundred and forty-two to one hundred and fourteen pounds. We are told also by cable that Dr. Henrik G. Peterson, a Norwegian, practising in America, tested the strength of the fasting man's grip on the dynamometer before he partook of food, and found that, it is said, it registered seventy-four pounds.

The Mississippi Medical Monthly is the name of a new journal edited by Drs. N. L. Clarke and H. H. Haralson, and published monthly at Meridian, Miss.

The Koch Institute for Infective Diseases.—This institution has at last been opened with due solemnity, with prayer and addresses by the clergy. There are already six cases of phthisis domiciled in it. Professor Koch's assistants are Staff-surgeons Pfeiffer and Behring, and Dr. Frosch, from the Hygienic Institute, and Dr. Petruschky, of Königsberg. Professor Brieger is at the head of the hospital department.

No More Artificial Teeth.—Old age is robbed of half its terrors and much of its deformity by the brilliant discovery of a Moscow dentist, Dr. Zuamensky, who, according to a possibly over-sanguine Russian contemporary, has delighted the civilized world by his skill in making teeth grow in toothless gums. After experimenting on dogs, he tried the effects of his method in human beings, and the success was complete. The teeth are made of gutta-percha, porcelain, or metal, as may be desired. The root of the false tooth has some holes bored in it. Holes are now bored into the jaw, and into the hole the false tooth is stuck as is a nail in wood. In a short time a tender growth starts up the cavity of the false tooth, and this growth hardening, the tooth becomes fixed in position. These new teeth can, according to the inventor, be placed in the alveolus of a natural tooth, and thus, when a diseased tooth is pulled out a metal or porcelain substitute can be inserted in its place, without incurring any risk of transferring disease, as happened in Hunter's days, when the apparently sound teeth of poor persons when transplanted, not infrequently conveyed disease. There are several minor inconsistencies in this statement, but it would be ungracious to look such a noble gift in the mouth, especially as, according to dentists of authority, our race is destined eventually to become edentulous.—*Medical Press.*

New Instruments.

A NEW LACHRYMAL DRILL.

By WILLIAM HOLLAND WILMER, M.D.,
WASHINGTON, D.C.

In answer to a letter written in May of this year, Tiemann & Co. replied, "There is no drill made for the lachrymal canal, as far as we know, and we have looked over many books. . . ." This reply was coupled with the offer to make a drill according to the writer's idea. Such an instrument has been made by that firm, and is presented in the accompanying cut.

The cut is two-thirds of the actual size. Attached to the tube, which has the curve of a Theobald's probe, is a flat supporting handle, serrated on both sides to prevent slipping. The octagonal handle for rotating the flat and sharp drill-point is of hard rubber, vulcanized to the shaft. The shaft is made of strong spiral steel, which readily takes the shape of, and freely rotates within, the cannula. The drill proper can readily be removed from the protecting tube for the purpose of cleansing.

The cases—bony closure of the lachrymal canal—for which the drill is adapted, are, of course, infrequent, but they do occur sufficiently often to render this instrument a useful addition to the armamentarium of the oculist.

The patient for whose relief this drill was designed gave

a history of repeated lachrymal abscesses for nearly two years. There was also a fistula at the site of a former incision. By the use of the drill, under chloroform, and the temporary after-use of a Princess style, syringing with an antiseptic solution, and by the periodical passage of a large probe, the young man has been able to resume his vocation (that of an artist), which had been abandoned at the onset of his lachrymal trouble.

Dry Gangrene in a Child Fourteen Months Old.—Dr. F. W. Monsell, of Port Pirie, reports in the *Australasian Medical Gazette*, vol. x., No. 5, 1891, a case similar to one reported in these columns by Dr. W. H. Hubbard, of Marion, Ind., about a year ago. The patient was a healthy girl, fourteen months old, of healthy parentage. One day shortly after having had an attack of vomiting, caused by the swallowing of some indigestible substance, there was noticed a little speck on the skin over the gluteus maximus. This was thought to be a spider-bite, as a black spider had been seen on the child's clothes that day. A doctor who saw the case ordered the spot to be poulticed. Three days later Dr. Monsell saw the child and found the skin inflamed with an indurated mass about half the size of a walnut, in the centre of which was a small gangrenous opening. This rapidly extended until it reached the margin of the labia, having an area of $2\frac{3}{4} \times 2$ inches. A tonic and stimulant treatment was adopted, antiseptic poultices being applied to the affected part. Under this treatment the progress of the disease was seemingly arrested, but soon swelling of several joints took place, purple patches appeared on the extremities, the skin acquired a waxy appearance, and the child died at the end of about two months. After death all the joints appeared to be dislocated, the skin over the spine and in other parts was purple, and the body was very limp, no rigor mortis having set in. The author believed that the spider-bite was the cause of the trouble.

Stamping out Small-pox.—Dr. J. M. Boyles, City Health Officer of Houston, Tex., relates in the *Abstract of Sanitary Report*, of January 26, 1891, an instructive history of an epidemic of small-pox in that city. On December 4, 1890, a circus arrived in Houston with a case of small-pox which was kept concealed until after the circus had left several days. On December 21st, small-pox made its appearance in several parts of the city simultaneously—in hotels, boarding-houses, etc. In less than five days there were 41 cases, mostly white. How many persons had been exposed at this time could not be estimated. At the suggestion of the Health Officer the City Council made vaccination compulsory. The house-to-house plan was adopted. Of the 21,000 persons vaccinated there was no bad effect—no amputations or deaths. Some suffered several weeks with sore arms. In forty days Dr. Boyles succeeded in getting the disease under control. Of the 349 cases no one contracted the disease that had been vaccinated under eleven years. Some vaccinated forty-nine years ago had varioloid, but of such a mild type it was not necessary to go to bed. There were 120 in the quarantine hospital that had been vaccinated and were exposed who did not take the disease.

A Cold Greenhouse.—One of the latest inventions in medicine is the use of cold greenhouses in tropical countries as a means of combating yellow fever. This disease can be conquered if one removes to those elevated regions in which oaks will grow. This fact recently inspired a celebrated Cuban physician with the idea of reducing the temperature of sick-rooms by artificial means, and wonderful cures resulted. Now it is proposed that in districts liable to the epidemic, each town shall erect a great glass house in which plants of cold and temperate regions may be grown, the temperature being artificially cooled instead of heated, as in our greenhouses, and that they shall be devoted to the treatment of patients suffering from the fever.

Rather Bad for the Eyes.—An esteemed correspondent from another State sends us the following prescription, which was written by a licensed physician, and presented to a druggist to be filled :

℞. Hyd. bichlor ..... gr. viij.
Mur. cocaine ..... gr. xxv.
Aquæ camph. ..... q. s. ad. ℥j.
M. S. : Shake, and put five or six drops in the eyes every two or three hours, when in pain.

The writer asks what effect such a mixture would have on the eye were the directions carried out, and also whether or not the ingredients of the preparation are compatible. The mixture would have a thick white precipitate, which would probably cause inquiries to be made, thereby perhaps saving the patient from a calamity.

Noeturnal Enuresis in Mouth-Breathers.—Dr. Otto Koerner says, that a very common cause of enuresis in children is the habit of mouth-breathing, and reports some cases in support of this view in the *Centralblatt für Klinische Medicin*, for June 6, 1891. In every case of wetting of the bed by children the physician, he says, ought to examine the little patient carefully to see whether there is any obstruction in the upper respiratory passages, and even if none be found the child should be observed when sleeping to see if it is not breathing through the mouth.

Congress of American Physicians and Surgeons.

Second Triennial Meeting, held at Washington, D. C., September 22, 23, 24, and 25, 1891.

(Continued from p. 370.)

THIRD DAY, THURSDAY, SEPTEMBER 24TH.

THE topic for the afternoon discussion was "Fibroid Processes (Chronic Interstitial Inflammation, Scleroses); their Pathology and Etiology, with Special Reference to the Influence of Diathesis and Heredity."

The discussion was opened by DR. ALFRED L. LOOMIS, of New York.

His paper dealt so fully with the subject that only the prominent features can be given.

In entering upon the study of the etiology and pathogenesis of fibroid processes it was well to state the objects of such study, viz.: 1. A classification, upon a pathological basis, of the fibroid developments. 2. The determination of the point at which the physical forces are productive of the first organic change in the series which terminates in fibrosis. 3. The determination of the consecutive order of changes in such arteries. 4. An estimation of the dynamic relations of diathesis to both the causes and the established processes.

There are two forms: 1, the hyperplastic (either atrophic or hypertrophic); and, 2, the inflammatory. In the pathogenesis of the first form, may be considered: 1, diminished nutritive supply, not reaching the point of necrosis; 2, parenchymatous atrophy; 3, nuclear proliferation; 4, connective tissue hyperplasia, or, in the hypertrophic variety, simple fibrous hyperplasia under direct stimulation. In the inflammatory form: 1, parenchymatous degeneration or necrosis; 2, constitutional influences producing lycocytosis; 3, positive chemotaxis, causing cellular infiltration, followed by organization.

The general etiology of fibroid processes may be briefly stated as follows: 1, all direct stimulants to fibrous growths; 2, all conditions inducing a limited decrease in the nutritive supply, viz., arterial fibrosis, embolism, pressure on vessels, vaso motor changes, etc.; 3, all conditions and elements which induce through perverted nutrition, either degeneration or necrosis. Under this last head may be included mechanical strain, pressure, defective nutritive supply, or tissue inactivity, and, most important, all tonic and trophic influences.

Diathesis determines the nature of the primary and predominant action, which will follow any given stimulant or irritant, when more than one is possible. It also modifies the ratio between an established process and its cause.

In arterial fibrosis, the following factors combine to produce necrosis and inflammation: 1, cellular toxæmia; 2, mechanical strain, possibly during hypertrophy of the muscular coat, but more probably during the muscular degeneration and relaxation which follows or accompanies the hypertrophy; 3, anæmia, from contraction of, and pressure on, the *vasa vasorum*.

In studying cardiac disease one is struck with the frequency with which arterial fibrosis is essentially localized in the coronary vessels, and for this there must be some special cause. Coronary fibrosis, the author thinks, may be, 1, local and purely traumatic; 2, part of a general change; 3, primarily traumatic, with a tonic exacerbation. We may accept, as more or less potent causes of cardiac fibrosis, 1, all tonic blood-elements and nervous atrophic influences which tend to prevent its parenchymatous nutrition by their action upon the assimilating power of its protoplasmic elements; 2, localized mechanical interference with the nutritive supply, as from changes in the arterioles; 3, traumatism, either of strain or compression.

In hepatic fibrosis we have, 1, cases in which the tissue necrosis is recognized as the primary change; and, 2, cases in which round-cell infiltration is the first appreciable change, and which are variously regarded as inflammatory or undetermined. The writer concludes that all hepatic fibroid processes are consequences of tissue injury, from three sets of commingled causes, viz.: 1, direct toxic action of the hepatic tissue elements, of which syphilis is a pure example; 2, mechanical injury through obstructed vessels and canals; 3, degenerative changes ending in necrosis, induced by excessive functional activity or special stimulation.

The multiple origin of fibroid processes becomes very prominent in renal fibrosis, and here it becomes necessary to classify the etiological elements into: 1, such as depend upon epithelial activity for their excretion; and, 2, those demanding an excess of blood supply in their elimination. Our most powerful stimulants to renal excretion give a soft, full pulse, and low tension. We may say, therefore, that those elements which are eliminated in solution under high tension, and increase the flow of blood, are productive primarily of arterial and interstitial fibrosis, through, 1, mechanical strain of the vessels incident to their dilated condition, coincident with the systemic contraction; and, 2, by interstitial compression, and later, malnutrition from diseased vessels. The epithelial cells suffer secondarily, and their changes speedily reach necrosis under the combined conditions of forced activity, malnutrition, and compression. It is an excellent illustration of the influence of heredity and diathesis.

We thus find in the kidney, as in other organs, that perversion of tissue nutrition is the first organic change in our fibrosis. This perversion is induced, 1, by cases of functional activity; 2, by the mechanical conditions developed, either physiological or pathological; and, 3, by direct tonic action upon the recent parenchyma.

In conclusion, the author said that it had been his endeavor to base all his arguments upon the generally accepted dicta of recognized authorities. He only claimed to have partially filled in some wide breaks in the fibroid processes.

DR. WILLIAM OSLER, of Baltimore, continued the discussion. His remarks were confined chiefly to a consideration of certain points of interest connected with interstitial processes in the central nervous system. The subject was a most difficult and perplexing one.

The connective tissue of the central nervous system is of two kinds: 1, neuroglia, special and peculiar, derived from the ectoderm, with distinct morphological and chemical characters; 2, that derived from the mesoderm, which is identical with the ordinary collaginous fibrous tissue of the body. Both play important parts in the indurative processes in the brain and cord. Sclerosis might be conveniently divided into: 1, the degenerative; 2, the inflammatory; and, 3, the developmental. The degenerative scleroses comprise the largest and most important division. They may be subdivided into: *a*, the common atrophic secondary degenerations; *b*, toxic

forms, under which may be placed the scleroses from lead and ergot, and most important of all, the posterior scleroses due, in a very large proportion of cases, to the virus of syphilis; *c*, the scleroses associated with changes in the small arteries and capillaries. As a senile process, a sclerotic atrophy of the convolutions is one of the most common of the cerebral lesions.

The inflammatory scleroses form a less important group. They might be divided into: 1. The secondary forms which develop in consequence of the reactive inflammation occurring about tumors, hemorrhages, foreign bodies, and in similar conditions. Histologically, they are pure mesodermic scleroses, and have a fibrous matrix similar to that which develops under like conditions in other parts of the body. 2. The sclerosis which occurs after a primary encephalitis or meningo-encephalitis. It is an acute process, occurring in the central nervous system as a result of the action of the poisons of specific fevers, and possibly also of syphilis. They terminate in a more or less extensive induration. In infantile hemiplegia, the onset is marked by severe constitutional disturbance, indicating an inflammatory process. The change is cortical and of variable extent. It is a frequent form of cerebral sclerosis, and may involve a few convolutions, or those of an entire lobe. 3. Developmental sclerosis forms a group to which, of late, especial attention has been paid. The diffused cortical sclerosis of children is the form which is best known, and which is met with as a congenital condition, and later in life, gradually producing atrophy of one hemisphere. Another form is the well-known overgrowth about the central canal, which constitutes the anatomical basis in syringo-myelia, the essential factor in which is the enormous proliferation of the neuroglia of the central gray matter.

The questions for discussion and for study hereafter, are: 1. What is the relation of the vascular change to the degenerative sclerosis? how far histologically are they mesodermal or ectodermal; or are they mixed, containing both neuroglia and collaginous connective tissue? 2. In the lobar scleroses of children, what is the nature of the primary affection; is it inflammatory, or is it essentially a lesion in the vessels? 3. In the developmental sclerosis, can we recognize a purely ectodermal form?

Chronic Fibroid Processes of the Spinal Cord was the subject of a paper read by Dr. C. L. Dana. He divided into, 1, primarily degenerative; 2, secondarily degenerative; 3, reparative and inflammatory. The scleroses included under the first head were primarily the result of the destruction of cells and fibres, and as examples of this class may be mentioned locomotor ataxia, lateral sclerosis, multiple sclerosis, and progressive muscular atrophy. The causes of the destructive process already mentioned are, either toxic substances, or the nutritive disturbance resulting from infection, and physical strain. These scleroses were not related to any diathesis. The French pathologists have shown the scleroses of the second class to be in all probability a proliferation of neuroglia, or a gliosis; the third class embrace those forms commonly known as chronic myelitis, diffuse myelitis, or transverse myelitis. They are a combination of simple necrotic, inflammatory, and secondary degenerative processes.

Dr. William T. Councilman continued the discussion, taking up the pathological anatomy. When a little pus is introduced, for example, into the liver, an area of necrosis occurs, and this is followed by an escape of leucocytes into the necrotic tissue. Much of the confusion which has arisen about this subject is due to confounding the leucocytes with a later stage in which there is a round-cell infiltration, and then the formation of new connective tissue. In the liver of typhoid fever small areas of necrosis are scattered all over its surface. It is important to remember that there is no known way of stimulating the growth of connective tissue; the tendency to growth and multiplication is always present, but the growth will not take place until the normal opposition to it is removed. We must always distinguish between an acute process causing a sudden death of the cells, and a slower and more diffused process with extensive infiltration of round cells. In general arterial sclerosis, we find a primary degeneration of the muscular coat, and the growth of connective tissue in the artery occurs as a consequence of this lesion in the muscular coat. The nature of the process depends upon the extent of the primary necrosis, and the character of the tissues in which it occurs.

Dr. Loomis referred in his paper to experiments on rabbits, in which a constant high arterial tension had been maintained by the administration of digitalis, and in which an endarteritis was developed. There was abundant clinical evidence to show that high arterial tension did not give rise to endarteritis. It was possible that in these experiments the digitalis itself may have produced the endarteritis.

Dr. Loomis here explained that he had expressly stated that the experiments were not entirely conclusive, as the result might have been partly due to the direct toxic action of the digitalis.

The time for adjournment having arrived, the President, Dr. S. Weir Mitchell, said that he had very carefully watched the work of the various component societies of the Congress, and had been much impressed with the earnestness and brilliancy which had been displayed.

President's Address.—Dr. S. Weir Mitchell, President of the Congress, delivered his address on the evening of Wednesday, September 23d. In speaking of the causes which led up to the organization of the Congress, the President spoke of the fact that specialism in medicine was of recent birth. He could remember when the older physicians refused to recognize socially a man who devoted himself to the eye alone. To day we can only look back with wonder at such narrowness. Cornelius Agnew once said that all would be better for an hour or two a day in a general hospital ward. It would be well for the young men of the profession who now select their specialty before they are weaned from the breast of their Alma Mater, to bear this saying in mind. Referring to the advantages and disadvantages of so much medical specialism, the speaker said that he was of the opinion that the gynecologists too often resorted to but one drug, and that steel in the trenchant form, when patient medical treatment might have preserved to the patients the inestimable possibilities of the wife and the mother. On the other hand, the general practitioner often sees the beginnings of disease, and does not correctly interpret them, or early enough ask counsel. Not only is the organization or this Congress exceptional, but it is one of national character, a collection of the ablest men in the American profession. There is much for such a body to do. Our climatology has yet to be investigated, and it is to be remembered that in no other country is there an extent of territory covered by weather reports which is such as to make its results medically available in relation to disease. As an example of this one need only recall Wharton Sinkler's interesting proof that the paralysis of childhood—acute anterior myelitis—is a disease of the summer months; Morris Lewis's masterly paper on "The Relation of Acute Rheumatism to the Storm Centres;" and his own study of "The Relation of Chorea to the Weather Curves," and of "Traumatic Neuralgia to Storms." We have also as yet to investigate our countless mineral springs. The swift social changes of this age and country await our future study.

Turning back from this bewildering view, let us catch a glimpse of some of the processes which have gone to the final making up of what is so well represented by this Congress—"Precision in Medicine."

Our precise methods of to-day require much time, and it certainly cannot be said that our instruments are labor-saving. A post-mortem section used to take us an hour or more; now, it goes on for weeks, in some shape, until

the last staining is complete, the last section studied, the last analysis made. While instruments of precision assist us greatly, they may prove stumbling-blocks to the thoughtless, or lazy, showing that it is necessary for men to always keep ahead of their instrumental aids.

The latter part of the sixteenth and the first half of the seventeenth centuries saw the birth era of instrumental accuracy in medicine, but many a day went by before the infant attained to useful manhood. The crude air-thermometer of Galileo was the beginning from which our modern instruments sprung, but his instrument was so inaccurate that he seems not to have valued it highly. In 1701, Newton marked the blood temperature at 12° of his scale, using linseed oil as the fluid in his thermometer. A little later, after several alterations of his scale, Daniel Fahrenheit at last set 96° as the blood heat; and here we first come upon the use of armpit temperatures.

The speaker next sketched the history of our knowledge of the frequency of the pulse, and of its relations to disease, dwelling particularly on the interesting development of methods of precision in studying the pulses, assisted by Galileo's pendulum or "pusilogon." In 1707, Sir John Floyer published a remarkable book, entitled the "Physician's Pulse Watch" The book also contains various observations on the relations of the pulse to age, exercise, sleep, and to various diseased conditions. His observations were, for the most part, thoughtfully carried out, and he evidently knew the world, for he predicts that, alas, too truly, his new methods will be sneered at and neglected. As late as 1768, we find Fouquet qualifying all pulse numerations as a mere useless curiosity, and sphygmometric instruments as idle toys. In 1796, Falconer says, "Floyer's methods were unused until now." The doctrine of the specific pulses, or a pulse for every malady, appears in countless volumes and survived up to the year 1827. This tale of the growth of precision in medicine is not without its moral. In every modern century were men who sought to secure it.

In conclusion, the speaker said that there must be many in the audience who knew that, apart from large human experience, and the material compensations of professional success, there was that in the mere pursuit of truth which mysteriously rewards from day to day. He was glad to think that this incessant every-day work is a talisman of content, a fact which none knew better than those to whom he now said his thanks and his farewell.

AMERICAN SURGICAL ASSOCIATION.

Twelfth Annual Meeting, held in the Grand Army Building, Washington, D. C., September 22, 23, 24, and 25, 1891.

(Continued from p. 372.)

THIRD DAY, THURSDAY, SEPTEMBER 24TH.

Recurrence of Cancer of the Breast.—DR. FREDERICK S. DENNIS, of New York, opened the discussion on this subject. Only those cases were included in which a microscopical examination of the tumor has been made. The necessity of an investigation of carcinoma of the breast is shown by the fact that in England alone seven thousand deaths occur annually from carcinoma, and a large proportion of these are cancer of the breast. It has been demonstrated that cancer is a disease which is slowly increasing in civilized nations. A study of the subject shows that there are seventy-five per cent. of recurrences. These include cases of incomplete operation, *i.e.*, when the axilla has not been opened. In the primary growth at the beginning, the neoplasm is of local origin. Early and complete removal of the growth relieves the local disease, but the operation does not relieve the predisposition, or susceptibility, or the capability for the recurrence of the disease. It is possible that the capability is limited to certain extent.

The recurrence of carcinoma of the breast is influenced, first, by the period of time from the appearance of the growth to the date of the operation. In the cases of the author in which the cure had continued for three years of more, the tumors were removed on an average six months from the date of their first recognition in the breast. In all the cases of permanent cure, the axillary glands were not invaded.

Recurrence is influenced, second, by the extent to which infiltration has taken place by any one or all of the three well-recognized ways of dissemination. When the tumor has existed long enough to show extension in these directions, the growth has been of long duration

Third, recurrence is influenced by the radical character of the operation itself. Complete removal of the breast is essential. The method of Mr. Stiles, of Edinburgh, by which the tumor after removal is treated with dilute nitric acid, in order to show whether or not the incisions have been made in healthy structures, and all the diseased structure has been removed, was described. The reported mortality of the operation is high, but in the author's seventy-one cases there had been but one death, and that was from continued bleeding in hæmophilia. In operation, not only the breast, but the axillary glands in most cases.

Fourth, recurrence is influenced by the histological character of the carcinoma itself. Where the structure differs slightly from the normal the clinical history is favorable. In none of these cases was there recurrence. Where there is great departure from the normal type, the clinical history is unfavorable. The more embryonic the structure the greater the chance of recurrence.

Fifth, the recurrence is influenced by the simultaneity in both breasts. This occurs in five per cent. of the cases. These patients are very liable to recurrence.

Sixth, recurrence is influenced by the personal factor of the individual, such as age, sex, marriage, fecundity, sterility, pregnancy, traumatism, heredity, menstruation, metastasis, mental condition, locality, etc.

Seventy-one cases of carcinoma of breast which had been operated on were referred to. In one there had been death from hæmophilia. In nearly all the axilla was opened. The operation consisted of excision of the entire breast, with all contiguous skin, the para- and perimammary, fatty areolar tissue, the pectoral glands, the pectoral fascia, and also removal of the axillary glands and fatty axillary tissue. In some cases the supra-clavicular glands were removed, and in one case excision of the ribs was done. The percentage of permanent cures amounted to thirty per cent. The author held that with early and radical operation recurrence of carcinoma of the breast will be comparatively rare.

MR. THOMAS BRYANT, of London, believed firmly in the local origin of carcinoma, although we must admit that there may be a predisposition on the part of the patient to the development of the disease. The disease should be treated at an early period, and this brings us to the question of diagnosis. Many cases do not come under observation until the disease is well advanced, because the patient imagines that a disease unassociated with pain cannot be cancer. Where induration appears in a breast during the period of functional activity, there may be some hesitation in the diagnosis; but in some thirty cases of this kind he had recommended immediate operation, and in all the cases the disease was shown to be malignant. In none has recurrence taken place. When the disease has advanced somewhat further, with dimpling and puckering of the skin and some immobility, we may get a good result by making a thorough operation. He had had some cases without recurrence for from five to twenty years. In the more advanced cases the surgeon should limit his operations to those in which there was a reasonable prospect of removing all the diseased structure. He does not remove the axillary glands in every case. If the glands be enlarged or the disease extend upward in that direction, he removes the glands thoroughly. Where the disease is quite local and there is no evidence of axillary involvement, the axilla is not opened. In the

atrophic form of cancer he thought it better not to interfere unless the tumor was giving rise to great inconvenience. Operation in these cases is often followed by a more rapid form of growth. Again, in this form of cancer where the lymphatics can be traced distinctly and the breast has a brawny feel—the lymphatic form of cancer—the surgeon does no good by interference.

Sir William MacCormac, of London, thought that the axilla should be opened in operation for carcinoma of the breast, for two reasons, viz.: An examination of one hundred and seventeen cases of cancer of the breast showed that in all but two there was axillary involvement; and, second, in ninety per cent. of the recurrences the disease appears in the axilla.

Dr. Lewis S. Pilcher, of Brooklyn, thought that the term "recurrence" was not applicable to many of these cases, and that in many the disease was simply a continuance of the former growth. If the case goes one year without the appearance of return of the disease, it may be considered that the disease has been removed, and if it appear later, it can be regarded as a recurrent, a renewed, or a new attack of cancer. In every case of cancer there is a predisposition to the disease, and we should search for some agent to counteract this constitutional predisposition which we can use in addition to operative measures. Arsenic has for many years been used for this purpose. Dr. Wight, of Brooklyn, has suggested the use of carbonate of lime for the same purpose.

Dr. L. McLane Tiffany, of Baltimore, did not think that we could set any limit to the time at which recurrence might take place He had had the disease return eight years after operation. He was a firm believer in the local origin of cancer. The date at which the disease is recognized varies much. In some the disease comes before the surgeon shortly after its commencement, while in others the tumor has reached considerable size. The time at which the disease is discovered by the patient bears no relation to the time of its commencement. Too much stress had not been laid on the necessity of thorough operation. In only two cases out of eighty operations for cancer of the breast had he found the axillary glands not enlarged. The pectoral fascia should be removed, and at times portions of the muscle should be cut away.

Dr. Hingston, of Montreal, believed that cancer was essentially a local disease. If we believe this, operation should be done at as early a date as possible. The glands should be removed not only from the axilla but from its neighborhood, if they are enlarged, but this should not form a necessary part of the first operation. Such a procedure adds greatly to the discomfort and to the danger. Where there is the slightest suspicion of involvement of the glands, they should be removed. If there should be recurrence, the operation should be repeated as often as circumstances seem to warrant.

Dr. Joseph Ransohoff, of Cincinnati, reported thirty cases of removal of the breast for cancer, without a death. He thought that the danger of the operation was not materially increased by opening the axilla.

Dr. C. B. Nancrede, of Ann Arbor, said with reference to the three year limit, that this had been proven to exclude ninety-eight per cent. of the recurrences. It is impossible to tell whether or not the axillary glands are involved without opening the axilla. Unless this is done the majority of the cases will be left unbenefited. He advised that the axilla be opened first, and if the glands could not be removed, to close the wound and not remove the breast.

Dr. J. R. Weist, of Richmond, Ind., had operated fifty-five times for cancer of the breast, and makes it a rule to open the axilla in every case.

Dr. George W. Gay, of Boston, felt that there was no such thing as a local origin of cancer as we have the local origin of a fatty tumor. When it can be shown that a cancer taken out will not return, just as a fatty tumor when removed does not return, then we can prove the local origin of carcinoma.

Dr. Edward M. Moore, of Rochester, always operates in as thorough a manner as possible. He always opens the axilla, and did not think that it added to the risks of the operation. He did not agree with Mr. Bryant in regard to the atrophic cases in old individuals. In these he recommended operation, considering recurrence very improbable. He reported one case living seventeen years after operation, and now seventy-nine years of age.

A Case of Diffuse Fibroma with a Tendency to Intracanalicular Growth of Both Breasts.—Dr. C. B. Porter, of Boston, Mass., reported a case of this nature. Mrs. M——, aged thirty-seven, resident of Nova Scotia, was admitted to the Massachusetts General Hospital. Has had two children, the youngest ten years of age. Three years ago she discovered a hard lump in the right breast which gradually increased in size. Three months later the left breast commenced to enlarge. The breasts continued to slowly enlarge until three months ago, when a rapid increase took place and the breasts soon became burdensome by their size and weight. On examination she was found to be pale, emaciated, and with ovarian facies. Right breast—largest circumference, 38 inches; length from chest-wall to nipple, 17 inches; circumference at base, 23 inches. Left breast—largest circumference, 28 inches; length from chest-wall to nipple, 14 inches; circumference at base, 23 inches. Throughout both breasts were felt movable, hardened masses of irregular outline, varying in size from an orange to a closed fist. It was decided to remove the left breast first. The breast was transfixed at the base with two skewers and constricted below this with a tightly drawn rubber tourniquet. The breast was then removed and but little blood lost. Three weeks later the right breast was removed. Twenty days after the second operation the patient was permitted to leave the hospital to visit friends, but instead she returned to her home, requiring a long sea journey. A week later she developed erysipelas. This had much improved in four days, when she suddenly aborted a five months' fœtus.

The weight of the right breast after removal was forty-three pounds, and that of the left seventeen pounds, a total of sixty pounds. A *résumé* of the reported cases was added.

Dr. J. M. Barton, of Philadelphia, reported a similar case on which he had operated, and in which one breast was involved.

Fourth Day, Friday, September 25th.

The committee to which was referred the suggestions in the President's address, offered the following resolution, which was adopted:

Resolved, That the President appoint a committee, with authority to confer with the friends and admirers of Professor S. D. Gross, and with the profession at large, for the initiation of a movement on the part of the Association, having for its object the erection of a monument to Dr. Gross, in the City of Washington.

As the matter is an important one, the President stated that he would announce the committee in a few days.

Treatment of Fractures Involving the Elbow-joint.—Dr. Lewis A. Stimson, of New York, read a paper with this title. The special interest of the subject arises from the frequency with which fractures of the lower end of the humerus are followed by more or less diminution of the functions of the elbow joint, and by deformity of the region or of the limb. The paper was devoted mainly to a consideration of the causes of these unfavorable results.

Causes of Limitation of Motion.—Permanent stiffness after simple fracture is commonly due to change in the shape of the articular surfaces or in their relations to one another, that destroys the coincidence of the axis of curvature with that of motion, or to an overgrowth of bone upon the surface of the humerus, arresting the movement

of the olecranon or coronoid process, or to more or less extensive ossification of the ligaments and capsule.

Overgrowth of bone from traumatism is more frequent in the young than in the adult. As limitation of motion may be caused by bony outgrowth from the humerus, itself the result of a persistent displacement of a fragment, or of separation of the periosteum, the most efficient way to prevent it lies in an exact diagnosis and reduction of displacement, and in the avoidance of any subsequent irritation of the periosteum.

Limitation of motion from thickening of the capsule and peri-articular tissues by the products of inflammation is as a rule a temporary condition. In the more permanent form the lesions are more extensive. The soft tissues are torn and a true cicatrix results. The thickened tissue may become ossified in whole or in part. This cause of limitation has been attributed, but improperly so, to prolonged immobilization and has led to the practice of passive motion in the early stages with the object of preventing its occurrence. Observation and experiment has, however, shown that immobilization is not itself a cause of anchylosis but that it is an efficient agent against inflammation, and that passive motion is powerless to prevent anchylosis when conditions contributory thereto are present; passive motion, therefore, is either harmful or useless. The primary cause of the exudation and of the proliferation of connective tissue that are the anatomical obstacles to motion is of course the original traumatism. The secondary cause is the following reaction. The only factor that can be increased or diminished by treatment is the second. That is the inflammatory reaction. Rest is universally admitted to be the best antiphlogistic measure that can be applied to an inflamed joint. An important disadvantage of rest at once suggests itself, namely, that the torn tissues may unite with shortening. So the clinical observation and theoretical considerations indicate that passive motion in the early stage does not avoid this disadvantage but actually increases it. In the present state of our knowledge it seems that a certain amount of limitation is unavoidable. Massage, however, hastens the absorption of exudation and the restoration of mobility, as does also permanent elevation or suspension of the limb. Reunion with shortening may be opposed by change in the attitude of the limb every few days. At a later period passive motion has its value, but in the early stages it is to be avoided. In regard to deformity, reference was made to only one, that commonly known as the "gun-stock" deformity, due to unreduced displacement of the internal or external condyle. In order to avoid this deformity the displacement should be reduced by pressure upon the fragment or by abduction of the extended forearm until its outward deviation is equal to that of its fellow, and immobilization by dressings that will not reproduce the displacement.

Treatment.—The first element in the treatment is the reduction of the displacement. If necessary, an anæsthetic should be employed. In supra-condyloid fractures permanent traction is usually necessary to overcome the displacing action of the flexors and extensors. This can be effected by vertical suspension of the limb, the patient being kept in bed, or by a weight suspended from the upper part of the flexed forearm while the patient is erect. The former method was recommended for the first fortnight of treatment, especially in compound fractures. Suspension is made by strips of adhesive plaster placed along the front and back of the forearm and attached to the support by indiarubber cords or a weight and pulley. In simple fractures the other method may be employed. The limb is encased in plaster-of-Paris with the elbow at a right angle, the wrist being placed in a sling and a weight not exceeding five pounds suspended from the elbow.

In inter-condyloid fractures with marked separation there is no practicable means of surely maintaining reduction, and considersble limitation is to be expected. In these cases a broad or heavy posterior splint, covering about two-thirds of the circumference of the limb, the elbow being at a right angle, was recommended.

In fractures of either condyle the treatment is by a posterior rectangular splint, either of metal or plaster. The forearm has been supported across the chest by a sling at the wrist. In some cases treatment in full extension has been employed. After this method has been employed for the first ten days or a fortnight recourse is had to the position with the elbow at a right angle.

Gentle Massage will Hasten Convalescence.—It may be advisable to change the position of the limb during treatment, and if great limitation is to be expected that attitude should be given to the joint in which, if stiff the usefulness of the limb will be greatest. In supra-condyloid and inter-condyloid fractures the splint should be worn six weeks, and in fractures of the condyles for about four weeks. After removal of the splint, the arm should for a few days be supported in a sling if necessary. Passive motions may at this time be resorted to, to increase the range of motion.

Dr. N. P. Dandridge, of Cincinnati, agreed with what had been said by the reader of the paper, and referred to two cases occurring under his observation. In one case of simple fracture from great violence, in which non-union had occurred, the arm was treated in a position of almost complete extension. The second case was one in which, after fracture at the elbow joint, a projection of bone pressed upon the median nerve, causing severe pain and atrophy of the muscles in the distribution of the nerve. The case was seen three months after the accident. Removal of the bone was followed by relief of the pain and a gradual restoration of the functions of the muscles.

Dr. R. A. Kinloch, of Charleston, thought that in simple fractures about the elbow, if seen early and the ordinary principles in regard to the treatment of fractures be applied, the result would be good. Probably in a large number of cases we must expect some restriction of movement. The most important element in the treatment is the proper reduction of the fragments. This should be done at once, an anæsthetic being employed if necessary. The proper reduction of the fragments is determined by testing the functions of the joint. The second indication is to retain the fragments in the proper position. If the case is treated with intelligence it makes little difference what way the splint is applied or whether it is treated in flexion. The position is to be determined largely by the peculiarities of the individual case. He was himself inclined to favor the extended position. In regard to passive motion, used early, he thought that it did more harm than good. If the parts have been properly reduced and held in position and there is danger of subsequent trouble passive motion may begin in three or four weeks.

Dr. E. M. Moore, of Rochester, said that in a fracture of the internal condyle the cause of the displacement is the flexor muscles, and to relax these muscles the arm is to be placed in the flexed position. In fractures of the external condyle he had also found this position the preferable one, for when the forearm is flexed the dense fascia on the front of the arm is rendered tense and acts as an efficient splint. He objected to the extended position entirely. He treats all fractures about the elbow-joint with the exception of fractures of the olecranon in the rectangular position for the first ten days or two weeks. Lateral splints are used with the object of pressing the fragments together. After the tenth day the fracture is dressed every other day, the angle of the splint being changed a little each time, so that the arm passes from almost complete flexion to almost complete extension. He had never had the slightest difficulty in any case since adopting this mode of treatment.

Dr. James McCann, of Pittsburg, said that it was not always easy to determine the exact nature of these fractures about the elbow-joint even with the patient under the influence of an anæsthetic. While the patient is

under the anæsthetic the preliminary dressing should be applied. He recommended the use of the internal angular splint, preferably that suggested by Dr. Packard. He did not favor the use of passive motion at an early stage. Passive motion should not be resorted to prior to the twentieth day.

Dr. John B. Roberts, of Philadelphia, thought that the teaching advocated by some of the speakers was to a large extent dangerous and incorrect. That is, that injuries about the elbow-joint should be treated in the flexed position. He believed that, except in unusual cases, these fractures should be treated in the extended position, according to the doctrine advocated by Dr. Allis. In this way the gun-stock deformity is avoided. He now approached fractures of the elbow with the same certainty of getting a good result as he did fractures of the lower end of the radius.

Dr. S. H. Weeks, of Portland, dwelt upon the fact that all authorities, with few exceptions, advised the flexed position in the treatment of fractures about the elbow-joint. Until there was more positive evidence of the value of the extended position he thought it better to continue to treat these fractures in the flexed position. He employed passive motion in a modified way. After two weeks' treatment the splints are removed and the joint moved gently, but not sufficiently to cause pain. This simply alters the relations of the parts without doing any damage.

Dr. L. McLane Tiffany, of Baltimore, thought that as good results were reported from various dissimilar methods of treatment we must conclude that the prognosis of elbow injuries depended more upon the patient than upon the surgeon. Fracture of the elbow is rare in adults and common in children, and in children with reasonably good treatment there should be a good result, and by the time adult age was reached the motion would be almost perfect. In the adult the prognosis is more grave. He had had good results both with the flexed and with the extended position in compound fractures. The secret lies in the relief of tension, irrespective of the apparatus employed. Incision up and down the arm through the strong fascia should be made as freely as may be required.

Retro-peritoneal Tumors.—Dr. Albert Vander Veer, of Albany, read a paper on the "Anatomical Relations, Pathology, Diagnosis, and Treatment of Retro-peritoneal Tumors." As our experience in abdominal surgery increases, we find that there are yet many problems that confront us, and of these problems there are none which requires more careful research and is capable of greater improvement both in operative management and in prognosis than new-growths arising from the retro-peritoneal space. In order to bring this subject more fully to the attention of the Association, the following cases are reported:

Case I.—Miss S——, aged forty-two, consulted the author in March, 1882, on account of a tumor located in the back. This was first noticed fifteen years previously. Examination showed a large tumor attached to the right side of the spine at the level of the first lumbar vertebra. It seemed attached to surrounding tissues, was of a smooth contour and hard to the touch. Operation was advised but declined. The tumor continued to increase in size until November, 1888, when she died from other causes. The autopsy showed the origin of the growth to be the connective tissue about the right kidney. It was encapsulated and could have been easily removed. It weighed eight pounds. The microscope revealed the presence of fat and myxomatous tissue with an abundant small round-cell infiltration.

Case II.—Mr. V——, aged forty-one, married, was first seen May 28, 1889. Five years ago strained his back. The pain following this has not been relieved by any treatment. Three months ago he became worse, the abdomen began to enlarge. The pain was more severe. He lost appetite and flesh. The ankles became œdematous and a distressing cough developed. The urine was scanty and high-colored but free from albumin and casts. The abdomen was more prominent on the right side. Fluctuation could not be elicited but palpation gave an impression similar to that of a lipomatous tumor. On the right side there was flatness from the nipple to the crest of the ilium, with the exception of a narrow space along the border of the ribs where there was a zone of resonance. The probability of the growth arising from the kidney was strong and an exploratory abdominal section advised. This was done June 1, 1889, an incision five inches long being made over the external border of the right rectus muscle. The growth was reached and the capsule divided, but from its attachments it seemed futile to attempt its removal. The patient recovered from the operation and for a considerable period was relieved of pain, the growth continued to increase in size, and the patient died October 21, 1889. The tumor, which weighed fifty-six pounds, originated behind the peritoneum and was attached to the right kidney. The microscope showed it to be an adipose tumor presenting a condition of myxo-sarcoma with sarcomatous infiltration.

Case III.—Mr. N——, aged thirty-nine, a brass-worker by occupation, began to have vague abdominal symptoms late in the year 1888, with failure of flesh and strength. In June, 1889, he developed jaundice, and a tumor was found in the left hypochondriac region and lumbar region. This was as large as a child's head. An exploratory operation was advised but refused. It was believed that the growth was connected with the left kidney. The tumor continued to grow, and in November, 1889, the patient died. The tumor was found to have sprung from the region of the left suprarenal capsule and involved it. It also surrounded the kidney. It weighed six and one-eighth pounds. The microscope showed an appearance similar to that in Case II., but with a greater preponderance of sarcomatous and myxomatous elements.

A careful study of the reported cases and of the literature of the subject impresses one with the belief that the most frequent origin of these growths is in the connective tissue of the capsule of the kidney, and that the next most frequent seat is the suprarenal capsule. None of these tumors can be said to be absolutely benign, even those which are made up entirely of histological elements, such as lipoma, fibroma, or myoma, while they show no great tendency to recurrence after complete removal, yet, from the great size to which they develop and their tendency to undergo degenerative changes, they cannot be classed as innocent growths.

In many of the reported cases the origin is not stated, and indeed it would, from the subsequent changes in anatomical relations, seem quite impossible to determine the exact origin of many of the large retro-peritoneal growths. They almost always present themselves in the line of least resistance, that is, anteriorly. Careful study of these tumors show them to be of a mixed variety, containing both the elements of the lipoma and myxoma tissues, which are histologically very closely associated. Fat is developed from embryonal mucin, and in post-fœtal life occupies those spaces in the economy which still later in the fœtus is of myxomatous elements. Doubtless many of these growths arise under suitable conditions from congenital neoplasms. These growths often become cystic, and reach immense proportions. They often present a numerous round-celled infiltration pointing to a sarcomatous element. Sarcoma, either in its typical form or in combination with other tissues, often occurs.

Diagnosis.—There is not a single symptom that is pathognomic, and the diagnosis is more dependent upon the process of exclusion. Tumors of the other abdominal and pelvic organs as well as aneurisms and tumors of the abdominal wall must be excluded. As already stated many of these tumors have their origin in the capsule of the kidney or the connective tissue surrounding it. These

present in their earlier stages at least physical signs differing in no respect from tumors of the nephritic parenchyma. In none of the cases reported has renal hemorrhage or albuminuria, with or without casts, occurred, conditions which are the rule with tumors of the parenchyma of the kidney. A valuable adjunct in the diagnosis consists in noting the relation of the tumor to the intestinal tube as shown by the insufflation of hydrogen gas.

Prognosis.—Without operative interference there is but one termination. The rapidity with which the fatal result is reached varies with the character of the growth. The mean duration of life, after the discovery of the tumor, is about nine months. Operative treatment offers much promise. The immediate mortality of the operation is great, yet, from the hopelessness of the condition, it is to be urged with great earnestness.

Treatment.—In operations for the removal of retro-peritoneal growths, the choice of incision will usually fall in the line of the linea semilunaris. By the separation of the peritoneum from the internal border of the tumor, it may be attached to the internal border of the abdominal wound, making the whole field of operation extra-peritoneal. The incision of the posterior fold of the peritoneum should be external to the attachment of the mesentery of the colon, although not absolutely necessary. In the removal of the growth by enucleation care should be taken to determine the source of the blood supply and the relations of the great vessels. There are likely to be large thin-walled veins deep in the wound, requiring ligature. At times it will be found necessary to remove the kidney with the tumor, as in all abdominal work the operator should be prepared for any and every complication. After enucleation the cavity must be thoroughly drained. The after-treatment is the same as in all other severe abdominal sections. Like all other conditions in surgery, there is certainly a better understanding of these cases going on. A more correct and early diagnosis, as is the case in all that pertains to medicine and surgery, will surely bring a larger percentage of recoveries. These are purely surgical cases—no medicines, no mineral waters or baths, electricity, or other lines of therapeutics having, as yet, been of any service.

To the paper was appended a complete bibliography of retro-peritoneal new-growths.

Bronchotomy through the Chest-walls for Foreign Bodies Impacted in the Bronchus.—Dr. DeForest Willard, of Philadelphia, read a paper on intra-thoracic surgery. He gave the results of a number of experiments on dogs in which an opening was made in the chest-walls, one or more ribs excised, and the bronchus thus reached either anteriorly or posteriorly. The operations were all fatal. The following conclusions were presented: 1. In dogs the bronchus can be reached either anteriorly or posteriorly through the chest-walls, but the anatomical position is in such close proximity to large and important structures that safe incision is a matter of extreme difficulty and danger. 2. Bronchotomy through the walls of the thorax is an operation attended with great shock from collapse of the lungs, and until the technique is further advanced is liable to result in immediate death. 3. Collapse of the lung is more serious in a healthy organ than in one previously crippled by disease. 4. The serious inherent difficulties are shock, suffocation from lung collapse, enormous risks of hemorrhage from pulmonary vessels, injury of, or interference with, the pneumogastric nerve, great and fatal delays, owing to the exaggerated movement of the lung caused by the excessive dyspnœa. 5. Closure of the bronchial slit is slow and dangerous. To leave it open causes increasing pneumothorax by its valve action, and also permits the entrance of septic air into the pleural cavity. 6. Although a foreign body can be reached by this route yet removal is hazardous. To secure a subsequent complete cure seems in the present state of knowledge very problematical. 7. When the presence of a foreign body in the bronchus is definitely determined, and primary voluntary expulsion has not been accomplished, there is great danger in permitting it to remain, even though it may but partially obstruct the tube. The risks both of immediate and of subsequent inflammation are serious. 8. Low tracheotomy is then advisable when the presence of a foreign body is certain. It adds but little to the risks, and affords easier escape for the object, even when extraction is not feasible. 9. Subsequent dangers arise from severe and prolonged instrumentation, not from tracheotomy. 10. Voluntary expulsion is more probable after than before tracheotomy. 11. Tracheotomy is permissible even after an object has been long in position unless serious lung changes have resulted. 12. The question of tracheotomy will depend largely upon the form, size, and character of the foreign body. 13. The term bronchotomy should be limited to an opening of the bronchus, and should not be employed to designate higher operations. 14. The risks from thoracotomy and bronchotomy following unsuccessful tracheotomy are much greater than the dangers incurred by permitting the foreign body to remain.

Dr. J. R. Weist, of Richmond, said that from a study of one thousand cases in which a foreign body was impacted into a bronchus, he had reached the conclusion that the chances of the patient were better if left alone than if an operation of what was formerly called bronchotomy was done.

Dr. S. H. Weeks, of Portland, thought that in these cases tracheotomy should be performed, as this affords a chance of reaching the foreign body, and also offers a chance for the spontaneous expulsion of the body. It occasionally happens that the body is forced up against the vocal cords and then falls back or else suffocates the patient before relief could be afforded. He reported the case of a child, ten years of age, who had gotten into the trachea a screw-cap that was used to close a pocket-flask. It had been there several days before the patient came under observation. It was decided to open the trachea. This was done and the patient suspended, but the foreign body did not escape. The patient was then placed in the horizontal position and the attempt made to remove the cap with forceps. It could be felt, but not grasped. After working unsuccessfully for some time, the patient was again suspended and the attempt with the forceps renewed, and at once the body was grasped and removed. The patient made a perfect recovery.

Dr. Kingston, of Montreal, reported a case in which he had removed an artificial incisor tooth with its attachments from the trachea, where it had remained for three months. The operation necessitated prolonged manipulation but was followed by no bad results.

Mr. Howard Marsh, of England, thought that on account of the danger of leaving the foreign body in the bronchus, the uncertainty in regard to the possibility of removal until the attempt is made, and the safety of tracheotomy, operation should be performed. The operation should be performed in all these cases, as it gives the patient a chance where otherwise he perhaps has none.

Mr. Arthur Edward Durham, of London, agreed with the author of the paper, that the operation through the chest-wall was a dangerous and doubtful procedure. The more he saw of these cases the more satisfied was he that the proper thing to do, where there is clear evidence that a foreign body is impacted in the bronchus, is to open the trachea, low down, and endeavor to remove the foreign body or to facilitate its spontaneous expulsion. This opinion was the result of considerable experience.

Dr. Louis A. Stimson read a paper on "Old Unreduced Dislocations of the Elbow."

The following papers were read by title: "Fractures Involving the Upper Third of the Femur, Exclusive of the Neck," by Dr. O. H. Allis, of Philadelphia; "Fractures of the Bones which Form the Elbow-joint, and their Treatment," by Dr. Levi C. Lane, of San Francisco; "Hemiplegia with Aphasia, following Ligature of the

Common Carotid Artery," by Dr. J. Ewing Mears, of Philadelphia; "Investigation of Pistol-shot Wounds of the Skull, and their Treatment," by Dr. E. H. Bradford, of Boston; "The Results of Experiments in the Filling of Cavities of Bones following Operations for Caries," by Dr. E. H. Bradford, of Boston.

Election of Officers.—The following were elected officers for the ensuing year: *President*, Dr. Phineas S. Conner, of Cincinnati; *First Vice-President*, Dr. L. McLane Tiffany, of Baltimore; *Second Vice-President*, Dr. Levi C. Lane, of San Francisco, Cal.; *Secretary*, Dr. J. R. Weist, of Richmond, Ind.; *Recorder*, Dr. J. Ewing Mears, of Philadelphia; *Treasurer*, Dr. John B. Roberts, of Philadelphia; *Member of Council*, Dr. Claudius H. Mastin, of Mobile.

The committee recommended the following resolution, which was adopted:

Resolved, That the Association hereafter hold each triennial meeting at Washington, and that other annual meetings be held at such time and place as the Association may name.

After extending a vote of thanks to the retiring president, the Association adjourned to meet in Boston, Mass., in June, 1892.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-seventh Annual Meeting, held at the Arlington Hotel, Washington, D. C., September 23, 24, and 25, 1891.

FIRST DAY, WEDNESDAY, SEPTEMBER 23D.

HASKET DERBY, M.D., PRESIDENT.

AFTER a brief executive session DR. D. WEBSTER, of New York, reported a series of cases of Cataract Extraction, which will appear in the MEDICAL RECORD.

Occurrence, Prevention, and Management of Prolapse of the Iris in Extraction of Cataract.—DR. H. KNAPP, of New York, read a paper on this subject. From June, 1886, to September, 1891, he had made 564 extractions, of which 53, or 9.5 per cent. were with iridectomy. Of the remaining 509 "simple extractions" 42, or 8.2 per cent., had prolapse of the iris in various degrees. The smaller ones were in the majority, and either disappeared or remained small and did no harm. To prevent prolapse observe the following rules: 1. Make an iridectomy when in the particular case, all points considered, the combined operation offers the better chances for the restoration of sight. 2. Cocainize thoroughly except in old, emaciated people, keeping the eye closed during cocainization. 3. Shape the corneal incision in the classical way, beginning near the horizontal meridian and continuing in the same plane near, never encroaching upon, the limbus. 4. Cleanse the pupil and anterior chamber thoroughly. 5. Open the capsule by one long horizontal incision in the upper part beneath the iris. 6. Avoid prolapse of the vitreous and any rupture of the zonulo-capsular septum of the eye. 7. Carefully reduce the iris. 8. During the first day or two keep the patient as quiet as his general health and reasonable comfort permit. 9. Watch the patient or tie his hands in sleep during the first week. The majority of prolapses are traumatic.

Treatment.—Leave the prolapse alone for at least ten days. It may be cut on the second day, but the results of cutting it from the third to the tenth day have not been favorable—suppuration occurred in one case, and iridocyclitis with sympathetic ophthalmia, in another. The failures of simple extraction have been very rare. The occurrence of prolapse of the iris has been the dark side to this operation. It is hoped that the number of cases in which it occurs will be reduced to a minimum.

Syringing Out of Cortical Matter in Cataract Extraction.—DR. J. A. LIPPINCOTT, of Pittsburg, reported a series of 100 cases in which this procedure had been carried out. The form of operation was a modified Graefe operation with a small preliminary iridectomy. The capsule was freely lacerated, and the cortex removed by lavage. Prolapse of the cornea occurred in four cases. It was quickly reduced by the stream of fluid from the syringe. Among the results there were but two failures, to which should be added one eye lost by suppuration following the preliminary iridectomy. In one case ether was given on account of the extreme restlessness shown by the patient at the preliminary iridectomy, the ether being indicated, not to prevent pain, but to overcome consciousness, since it was not pain but the excitement of fear that made the patient uncontrollable.

DR. HENRY D. NOYES, of New York, wished to remind the Society that prolapse was not confined to simple extraction but occurred after iridectomy, and was there attended with the same harmful consequences, although it was confined to the angles of the wound. The principal causes of prolapse, he believed, were a condition of increased tension of the globe before the operation and subsequent uncontrollable squeezing together of the lids.

Coloboma of the Iris, Polycoria, and Primary Glaucoma.—DR. GEORGE E. DE SCHWEINITZ, of Philadelphia, reported a case of this kind occurring in the left eye of a woman aged fifty-two. The glaucoma ran a subacute course with a number of glaucomatous attacks, in one of which iridectomy was performed. The affected eye had the congenital defects named above, and several areas of exudative retino-choroiditis. The coloboma had the usual situation—downward and slightly inward—in addition to which there were three apertures, mainly in the upper and inner quadrant, one of which was crossed by two fibres of persistent pupillary membrane. On the capsule of the lens was also a small tag of brownish color, probably the remains of the capsulo pupillary membrane. Although such congenital defects would apparently interfere with the theory of the dependence of increased tension on the closure of the filtration angle of the anterior chamber, the investigations of Mr. Collins show that such cases confirm that theory. The case also substantiated the idea that polycoria, or so-called supernumerary pupils are due to defects in its tissue, arising from incomplete evolution of the choroid, or they are dialyses, separations of the attachments of the iris, and do not represent malformations due to arrested development. The retino-choroiditis was suggested as the primary cause of the glaucoma. Charts of the field of vision and colored drawings illustrating the appearances of the iris and the eyeground were exhibited.

Partially Bony Growth of the Orbit.—DR. B. L. MILLIKIN, of Cincinnati, reported a case of this nature in which the tumor was successfully removed. The patient, a girl of sixteen, had noticed at six years of age a small hard tumor in the upper inner part of the orbit, which developed very slowly with little or no discomfort. At nine years of age, she had an operation for its removal, the wound remaining open and discharging from April till September. The growth continued from that time until seen in June, 1890. Then the tumor involved the whole inner and upper portion of the orbit, extending outward to the junction of the middle and outer thirds of the orbit, and about an inch below the line of the eyebrow, with marked exophthalmos downward, outward, and forward. The optic nerve was partially atrophied with thread-like arteries; vision, $\frac{6}{6}$. The removal of the growth was undertaken June 17, 1890, when it was found to have a hard, bony covering with soft, fibrous, organized interior. It was all removed, a small drainage-tube inserted, and dressed with bichloride gauze. On the thirteenth day the wound was entirely healed, and the patient left the hospital in good condition. No return has occurred within a year and a half. The microscope showed it to be a spindle-shaped sarcoma with numerous points of fatty degeneration, simulating small cyst cavities.

Scholer's Operative Treatment of Detached Retina.—DR. CHARLES S. BULL, of New York, read a paper on

this subject. He first gave a review of the history and literature of the subject, and then reported five cases of his own in which it had been resorted to. His conclusions were distinctly unfavorable to it. In the first case, a man, aged thirty-eight, with history of a blow on the eye and improper use of the organ, on whom other treatment had been ineffective, three drops injected slowly caused a temporary clouding of the vitreous, with great diminution of vision, followed by return of vision to its original condition without any improvement of the de tachment, or of the visual field, and with formation of a band of cicatricial tissue that must pull upon the opposite part of the retina, and perhaps would lead to a total detachment. The second case, a woman, aged thirty-one, had much the same experience; was left the worse for the operation, with no improvement of the detachment. But in these the inflammatory reaction was remarkably slight. The third and fourth cases were in men, aged sixty and seventy-three. In them a panophthalmitis occurred, causing complete loss of vision in one, and considerable deterioration in the vision of the other. In the fifth case, the ultimate result was an increase of the detachment.

Brain Tumor.—Dr. Bull also reported the following case: The patient came for persistent inequality of the pupils, and was found to have paresis of the internal recti and hyperphoria. He had a history of syphilis, and suffered from attacks of apparently petit mal and lapses of memory. Vision was, right eye $\frac{20}{30}$, and left eye $\frac{20}{20}-$. The fundus of the right eye showed a moderate neuro-retinitis, the left only the usual changes of a myopic eye. Mercurials and large doses of potassium iodide were given, and the optic neuritis improved and entirely disappeared. But very marked hemianæsthesia developed. An eminent neurologist made the diagnosis of cerebral sclerosis. He continued without marked change for many months, then was seized one night with intense pain in the head (having been previously free from headache) and died next morning. The autopsy showed a large gliosarcoma in the left frontal lobe.

Significance of Macular Changes in Advancing Myopia.—Dr. Hasket Derby, of Boston, read a paper on this subject, in which he advanced the idea that the macular changes of pigmentation and hemorrhage in sclerotico-choroiditis posterior, rarely coincide with, or are followed by retinal separation. This involves the probability that the latter accident will never take place, and enables us to predict the probable permanent retention of a certain amount of vision for the remaining years of life. Such was Dr. Derby's experience, and he invited the attention of others to this point.

Orbital Traumatism with Immediate Monocular Blindness.—Dr. Peter A. Callan, of New York, reported two cases of this kind. The first was injured while fencing by the point of a foil, which penetrated his mask and entered the right orbit between the globe and the nose. The eyeball remained intact, but was displaced down and out. When seen forty minutes after the accident, the right eye was entirely blind, pupil dilated ad maximum and ball immobile. There was no light perception, and atrophy of the optic nerve came on in three months. The second case was that of a man, assaulted by a rival and struck over the left eye, stunning him for a moment. On recovering from the dizzy feeling he found that the vision of his right eye was gone. Fifteen hours after the assault the right eye was found blind with widely dilated pupil, but the movements of the ball not impaired. In seventy-two hours right ptosis had developed, and in ninety six hours there was ophthalmoplegia externa, and subsequently atrophy of the optic nerve. The left eye was not materially injured.

Pulsating Exophthalmos—Ligature of the Common Carotid.—Dr. R. A. Reeve reported a case of this nature. The condition developed in a young man from a kick on the side of the head. Intermittent compression checked the pulsation and purring bruit, but, though continued hours at a time for three months, produced no permanent effect. The common carotid was tied, and he recovered from the operation without complications, but in seven hours the purring bruit recurred. Intermittent compression of the other carotid has proved insufficient, and its ligation is proposed.

Operative Treatment of Divergent Squint.—Dr. E. Gruening, of New York, described a method for the treatment of this affection. The operation of tenotomy, as usually described in the books, was suited to the internal rectus muscle, but quite a different operation should be practised on the external rectus. He had obtained satisfactory results by doing a free tenotomy through a free conjunctival opening, and by a ligature across the nose, tying the eyes in a position of strong convergence. In this way about two millimetres of divergence was remedied. For higher degrees it was necessary to do a resection, cutting out as much of the tendon as the excess of divergence over two millimetres when tested at one-third of a metre.

Heterophoria.—Dr. Swan M. Burnett, of Washington, offered some contributions to the study of heterophoria. He believed that disturbances of muscular balance gave rise to asthenopia, headache, etc., but less frequently does ametropia. In 100 consecutive patients, 22 exhibited heterophoria. Of 50 consecutive cases of heterophoria, 28 were of exophoria, 18 of esophoria, 3 of hyperphoria, and 1 of combined esophoria and hyperphoria. Theoretically, such conditions could be relieved by the wearing of prisms. But prisms are frequently unsatisfactory. By graduated tenotomy a nicely graduated weakening of the predominating muscles may be effected. The histories were narrated of five cases for which this measure had been resorted to. In four of these headache of the severest type and of years' standing had been thus almost entirely relieved. In performing the operation the extreme fibres of the tendon are left intact and a triangular piece excised from the centre.

Restoration of the Lower Eyelid.—Dr. George C. Harlan, of Philadelphia, described a modification of Dieffenbach's operation for restoration of the lower eyelid. When the surface from which the flap is taken is left uncovered, the cicatricial contraction that occurs tends to draw upon the flap, and also to draw down the outer canthus. The modification consists in filling in this space with another sliding flap taken from the temple, in which situation the cicatricial contraction is not likely to exert any injurious influence.

Skin-grafting by Thiersch's Method.—Dr. S. Theobald, of Baltimore, reported two cases of this operation for extensive loss of surface of the eyelid. The grafts were taken from the inner surface of the forearm in strips one-half inch wide, and placed in warm salt solution. No antiseptic was applied to the raw surface, but the granulations were shaved off and washed with warm salt solution. The cases were treated as out-patients.

Second Day, Thursday, September 24th.

Neuroma of the Right Upper Eyelid and Adjoining Temporal Region.—Dr. George E. de Schweinitz, of Philadelphia, reported a case of this affection. The tumor was congenital, and the lad twenty years of age at the time of operation. After the removal of the tumor a plastic operation was done for the relief of entropion, and Pana's operation for ptosis. The microscopic examination showed strands of soft connective tissue containing compressed and atrophied nerve-fibres. The gross appearance was that of elephantiasis. A large proportion of these tumors, as reported, have been situated in this region. Micro-photographs showing the structure of the growth were exhibited.

Vaseline in Gonorrhœal Conjunctivitis.—Dr. F. M. Wilson, of Bridgeport, read a paper with this title, in which he gave his experience with vaseline in 47 cases of the disease, 19 of them ophthalmia neonatorum, among whom two eyes were lost, and 28 in males over sixteen

years of age, with clear evidence of infection. Of these latter 12 were to be classed as mild cases and 16 as severe, all but two of which had ulceration of the cornea. The vaseline was used in connection with ice-cloths, atropine, cleanliness, silver nitrate, and bichloride. The vaseline is to be applied freely between the lids every hour or so, and allowed to make its way to every part of the cul-de-sac of the conjunctiva. It is not a mode of treatment to be used alone, but in connection with other means saves the cornea, and adds greatly to the comfort of the patient.

Roller Forceps for Pressing Out Trachomatous Granulations.—Dr. H. Knapp, of New York, exhibited an instrument for this purpose. At the end the forceps-blades are fixed to creased rollers, between which the tissue is firmly grasped, and as they are pulled away press out the infiltrated matter without much laceration, acting as a mangle or wringer in squeezing water out of clothes. He had used it in fifty-eight cases, and found that follicular trachoma could be permanently cured at one sitting without subsequent contraction or scars. Mixed forms are greatly benefited, but may require other treatment too.

Foreign Bodies in the Eye.—Dr. E. E. Holt, of Portland, Me., reported six cases of extraction of foreign bodies from the eye. In three of these the electro-magnet was successfully used for the removal of bits of steel. In two the foreign body was extracted with forceps, and in one that had been neglected for two weeks the vitreous had become fluid and the globe collapsed from the operation of removal.

Dr. S. B. St. John, of Hartford, reported three cases. In the first, a bit of iron was lodged in the iris, the magnet failed to dislodge it, an incision was made in the cornea, the iris drawn out, the iron disentangled, and the iris returned, the eye recovering with a free and almost circular pupil. In the second a piece of fine wire had remained in a child's eye for one month, transfixing the cornea, iris, and lens, and projecting into the vitreous. In the third the foreign body, a bit of steel, was visible near the macula, and successfully withdrawn with the magnet.

Brain Tumor.—Dr. L. H. Taylor, of Wilkesbarre, reported a case in which the symptoms began with headache and a fall, probably a fit, while playing tennis. When seen there was severe persistent headache, some staggering and weakness, vision equal $\frac{20}{30}$, with very high grade of choked disk. A year later there was complete blindness, with atrophy of the optic nerves, numbness of the face, and marked hemianæsthesia. Death was sudden, without much further change in the symptoms. The autopsy revealed a very large glioma, springing from the corpora quadrigemina and floor of the fourth ventricle, pressing up the posterior lobe of the cerebrum, causing a bulging of the dura and erosion of the skull. Except his first fall there was nothing like a convulsion, and no mental derangement.

Calibre of the Retinal Vessels after Injuries to the Head.—Dr. A. G. Heyl, of Philadelphia, reported some observations bearing on this subject, based on a series of twelve cases, comprising two groups. In the first, brain delirium, or its initial stage, existed; the retinal veins were of about normal calibre but rounded, and the arteries were contracted. In a typical case of simple contusion of the brain, as shown by autopsy, the vessels were first dilated, then passed into the condition above mentioned. In the second group there existed sopor alternans, in which short intervals of sleep alternate with similar periods of waking, and the pupils vary in diameter with these intervals, and in one case the retinal vessels were observed to do the same.

Amaurosis.—Dr. T. G. Sutphen, of Newark, reported three cases of this affection. In the first it followed suppression of menstruation due to a long walk in the snow. In the second case it followed parturition. In both of these, first one eye became blind, then the other, and there was subsequent atrophy. In the third there was complete loss of sight in one eye, without ophthalmoscopic changes, and subsequently there was partial recovery.

Quinine Amaurosis.—Dr. George E. de Schweinitz reported the results of additional experiments to determine the lesion in quinine blindness. His previous observations, reported in the *Ophthalmic Review*, were confirmed, that quinine in the quantity of from one to four grains to the pound in dogs causes blindness, without at first marked or ophthalmoscopic or microscopic changes, except in one case of thrombus of the central vein. Later, all the appearances of a true optic atrophy develop, sometimes associated with thrombosis or embolism of the central vessels. The atrophy causes cupping of the disk and extends back through the nerve-trunk, chiasm, and tract. There was also found some degeneration of the lenticular ganglion. Careful sections of the ciliary nerves and other cranial nerves showed them to be normal. The conclusions of these experiments were that the poisonous action of the quinine is originally due to a constriction of the peripheral vessels; that, later, distinct changes either in the blood itself or in the vessels may cause thrombosis, and complete atrophy and fatty degeneration of a large portion of the optic tract may occur. These conclusions are in accord with clinical observations and the investigations of others. The paper was illustrated by a beautiful series of specimens and microphotographs by Dr. Gray of the Army Medical Museum.

Eye Symptoms in Mongolian Idiocy.—Dr. Charles A. Oliver, of Philadelphia, presented the results of a clinical study of the ocular symptoms found in the so-called Mongolian type of idiocy. The irregularity of contour, size, and in the contents of the orbits, are expressions of the tendency to osseous and ligamental malformations characteristic of the disorder. The eyeball presents the results of low chronic forms of neuro-retinitis and choroiditis in intra-uterine or extra-uterine life. The head of the optic nerve and adjacent tissues share in the soft, jelly-like œdema so universally recognizad in the external portions of the organ. The mucous membrane of the eye and its appendages shares in the pathological peculiarities of such membranes throughout the body. The walls of the visible vessels appear thin and peculiarly tinted, and retinal hemorrhages occur, showing they share the imperfect development, with consequent disease of the entire vascular system.

Eye-Strain from Wearing Cylindrical Lenses.—Dr. Edward Jackson, of Philadelphia, called attention to this cause of eye-strain. Any line seen through a cylindrical lens, unless it be parallel or perpendicular to the axis of the lens, appears to have a false position, nearer parallel the axis of a concave lens, farther from the direction of the axis of a convex lens than its true position. When the cylindrical lenses before the two eyes are of different strengths, or turned in different directions, the images of the lines in the two eyes will be differently displaced, and to bring them on corresponding meridians of the retina will require a different relation of the rotating or oblique muscles from that to which they are accustomed. The extent of the rotation depends on the strength of the lens and its distance from the eye. So that for any given lens the amount of readjustment required can be reduced by bringing the lens closer to the eye, and with strong lenses it was important to have them brought as close as possible, even clipping the eyelashes at first is necessary.

Insanity following the Use of a Mydriatic.—Dr. Taylor reported a case of this kind. The patient, a young woman, had been subjected to severe physical and mental strain in looking after the wants of a family and waiting upon an insane mother. A four-grain solution of atropia was ordered for measuring the refraction, and used for two days without causing unusual nervousness or other symptoms; but on the third day she gave way to causeless, uncontrollable weeping and vain laments, and from that

time grew worse, and in a few months was placed in an asylum, with confirmed melancholia.

Hyoscyamine as a Mydriatic.—Dr. S. D. Risley, of Philadelphia, presented a note on this subject, calling attention to the fact that the preparations offered in the shops varied greatly in quality, and that to gain those advantages which had led him to use it very largely, it was needful to use only a pure crystalline preparation from the best makers.

Dislocated Lens.—Dr. Theobald presented additional notes on a case of this kind, reported to the Society in a former year. Since then the lens had become opaque and had been absorbed after discission. Vision was now improved by weak lenses, and a tag of capsule still remained hanging in the vitreous.

Accommodative Asthenopia.—Dr. Theobald also read a paper claiming that subnormal accommodative power is a not infrequent cause of asthenopia. The principal evidence of the condition is an excessive tendency to convergence at the working distance as compared with the balance of the muscles for distant vision. It is to be met by the wearing of convex lenses for all near work.

The Blind of New York City.—Dr. H. S. Oppenheimer, of New York, presented a statistical paper based on examination of those applying for relief from the city on account of loss of sight, to the number of 571, of which one-third are from the communicable, and therefore preventable diseases.

Optic Nerve Tumor.—Dr. John Green, of St. Louis, presented a colored drawing of the fundus, and described a case of colloid tumor of the optic nerve.

Glaucoma following Cataract Extraction.—Dr. F. Buller, of Montreal, reported three cases of glaucoma after cataract extraction done with iridectomy, but leaving dense pupillary membranes. In two cases the eyes were rendered blind. The third seemed to have the tension satisfactorily reduced by the use of eserine.

The officers chosen for the ensuing year were—*President*, Dr. Hasket Derby, of Boston; *Vice President*, Dr. George C. Harlan, of Philadelphia; *Secretary and Treasurer*, Dr. S. B. St. John, of Hartford, Conn.; *Corresponding Secretary*, Dr. J. S. Prout, of Brooklyn.

The Society adjourned, to meet at New London, Conn., the third Wednesday in July, 1892.

AMERICAN NEUROLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, held at the Arlington Hotel, Washington, D. C., September 22, 23, and 24, 1891.

(Continued from p. 374.)

Third Day, Thursday, September 24th.

Removal of a Neuroma, Followed by Disappearance of Anæsthesia of Fourteen Years' Standing.—Dr. G. L. Walton reported the case of a professional man, twenty-nine years of age, who had fourteen years previously cut the left index-finger with a chisel, thereby injuring the nerve. Complete anæsthesia had persisted. Within two years paræsthesia and pain in the entire hand and tenderness of the nerve-trunk, together with areas of anæsthesia and symptoms of neurasthenia. A neuroma was found in the course of the nerve and removed by excision. Sensation returned within four months after operation, the other symptoms gradually disappearing. The case was reported in order to show that the duration of anæsthesia is no contra-indication to operation on a peripheral nerve.

The Electro-physiology of Reflexes, with the Description of a Hitherto Unknown Localized Physiological Reflex Phenomenon.—Dr. George W. Jacoby read a paper on this subject (accompanied by a demonstration), in which he said that our knowledge of reflexes produced by electrical excitation is still in its infancy, and an electro-physiology of reflexes does not yet exist. The reasons assigned for this lack of knowledge are the necessity of employing very strong currents, and the difficulty of deciding whether contractions thus produced are reflex or not; these reasons he considers entirely invalid. After numerous experiments he discovered a reflex, produced by the application of the negative pole of a galvanic battery to the radial side of the forearm, which consisted in a contraction of muscles of the chin.

Examination of two hundred persons showed that the reflex was present in over seventy per cent. of normal individuals. The experiments were conducted by placing a large Erb electrode over the back of the hand and then making closure of the current with a small electrode attached to an interrupting handle. All such experiments upon the human body have heretofore been entirely dependent upon the statements and feelings of the patient. These unreliable factors can now be eliminated by utilizing the reflex described, as hereby we have a visible proof of the sensory reaction. Jacoby does not doubt that, attention having now been called to this reflex, other reflexes of a similar nature may be found in various parts of the body, and that we will by their examination obtain knowledge not only in regard to the pathological changes in sensory nerves, but also in regard to changes in that part of the cord upon whose integrity the excitation of such reflexes depends.

Supplemental Treatment of the Paralysis of Acute Anterior Polio-myelitis.—Dr. V. P. Gibney read a paper on this subject, and said that a palsied muscle, or a group of palsied muscles, is often very much handicapped by contractured tendons or muscles on the opposite side of the limb. Because of these contractures local treatment is often inefficient. However efficient the galvanic or the faradic current, or even massage, may be, if the muscle is overstretched the efficiency is certainly minimized. Another point was this, that a palsied muscle, or a group of palsied muscles, responds better to local treatment after a period of rest, or at least after being retained for a long time in normal position. In this connection he reported the histories in six cases. He advocated the correction of deformity, the removal of tension from a weakened muscle, the replacement of the joint surfaces to normal apposition, and the assistance generally given to a limb, the muscles of which are weak and palsied.

Intra-cranial Syphilis.—Dr. Landon Carter Gray read a paper upon the diagnosis of a certain form of intra-cranial syphilis, giving the histories of a number of cases in support of his views. These symptoms were a cephalalgia that is quasi-periodical, recurring generally at night, occasionally in the afternoon or in the morning, with marked insomnia; this cephalalgia and insomnia ceasing suddenly upon the supervention of any paralytic symptoms. Dr. Gray also called attention to the fact that a hemiplegia occurring in an individual under middle age should render us very suspicious of a syphilitic causation. This peculiar headache and insomnia belonged to the early stage of intra-cranial syphilis, although it might occur in the primary, secondary, or tertiary state of the general syphilitic infection.

Dr. Mills said that the occurrence of paralysis after the subsidence of headache and insomnia was an unimportant feature in the diagnosis or treatment of syphilis. These symptoms occurred in consequence of degenerative changes.

Dr. J. J. Putnam agreed with Dr. Mills, and mentioned three cases illustrating the supervention of paralysis on the cessation of headache and insomnia. He believed that anæmia or arterial congestion gave rise to the former condition, thus rendering the patient less sensitive to pain.

Dr. Hughes said that the persistency of the headache was of more significance than its periodicity.

Triple Personality.—Dr. Irving C. Rosse, of Washington, read a paper on this subject, and reported a case in exemplification of "triple delusions," occurring in a man, thirty-five years of age, who explained that in addition to himself he consisted of a "young man" and

"Lucifer." This mental condition had remained unchanged, with the exception of about three months of comparative inactivity of delusion nine months ago, since which time gradual impairment of the faculties has left the patient in a state of dementia.

Deformity of the Palate in Idiots.—Dr. Walter Channing, of Boston, presented a series of charts and plaster casts showing the formation of the palates of one hundred and fifty cases of idiocy. A prominent feature of interest was that this is the first time that any accurate observations with measurements had been made along these lines. From the writings of Dr. Langdon Down the impression had arisen that in nearly all idiots the palates were vaulted and V-shaped. Channing had classified his cases into average, neurotic, and deformed, showing a percentage respectively of forty-three, thirty, and twenty seven per cent.

Double Athetosis.—Dr. William Osler, of Baltimore, read a paper on this subject, based upon fifty-three cases in literature and numerous personal observations. He mentioned incidentally that this condition is compatible with a high degree of intelligence, but is usually accompanied by mental deterioration.

Lesion Locating the Auditory Centre.—Dr. Charles K. Mills reported a case probably accurately locating the centre for word hearing, in which there was a lesion of the first and second temporal convolutions of the left hemisphere. There was word-deafness following an apoplectic seizure. More complete deafness and partial left-sided paralysis following a second apoplexy. Autopsy showed lesions of the first and second temporal convolutions of both hemispheres.

Subcortical Hemorrhagic Cyst Beneath the Arm and Leg Areas.—Dr. Mills reported another case with the above title, with the view of emphasizing a single point in the differential diagnosis of a limited lesion of the motor subcortex.

Autopsy on a Case of Athetoid Spasm and Myotomia, and Diffuse Bilateral Disturbances of Sensation; Chronic Convexity, Meningitis of both Hemispheres with Cortical and Subcortical Softening, the Lesions being most marked in the Posterior Parietal Region.—The same writer reported an additional case with the above title.

Tumor of the Mid-brain and Left Optic Thalamus.—Dr. James H. Lloyd, of Philadelphia, reported the case and exhibited the specimen from a patient twenty-eight years of age, who had been admitted to the Philadelphia Hospital. There was a crossed paralysis, the left third nerve being involved, with right brachial monoplegia and right crural monoparesis. The face and tongue were not paralyzed on either side. No paralysis of any other cranial nerve. Death took place on the twentieth day after admission. The autopsy revealed a tumor of the left optic thalamus and the mid-brain, involving the left cerebral peduncle. On microscopical investigation this was found to be a glioma. A diagnosis of tumor of the left cerebral peduncle had been made at the first examination.

The last five papers were then made the subject of general discussion.

Dr. F. X Dercum said that the sensory features in Dr. Mills's cases would prove an interesting study.

Dr. J. J. Putnam referred to the autopsy, in which no lesion could be found, in the case of a child with double athetosis. In a case of hemichorea there was a distinct spot of softening in the tegmentum on one side. In another patient with locomotor ataxia and no impairment of intelligence, there was a linear subcortical hemorrhage, in the subcortical area below the paracentral lobule. Secondary degeneration had occurred in the cord. He also spoke of a case of sensory aphasia that was operated upon, with the result of finding a cyst occupying the left temporal lobe.

Dr. L. C. Gray mentioned the case of a man with hemiplegia and impairment of the muscular sense, in whom nothing could be discovered on operation. Death took place on the following day. Autopsy revealed a round-cell sarcoma with cystic degeneration in its centre, at the junction of the arm and leg centres. This was situated in the sub cortex. There was also a sarcoma of the thigh.

Dr. Mills asked if the paralysis was spastic.

Dr. Gray replied that it was not, but he thought that spastic symptoms generally occurred where the lesion was near the basal ganglia.

Dr. C. L. Dana cited the case of a man aged forty-six, who had syphilis ten years before. There were headache, left hemiconvulsions, and coma. He recovered with left hemiplegia and left hemianæsthesia. Autopsy showed a gumma of the dura over right central convolutions. In another case of a man aged fifty-five, with progressive right hemiplegia, and some loss of sensibility on same side, there was a tumor about the size of a hen's egg in the middle of the left precentral convolution. He also narrated the histories he had collected of several cases of similar character, showing localization of sensory centres. He held the view that the cutaneous sensations must have their representation in the brain cortex, and had a larger and more diffuse representation than the motor. When one side was affected, compensation would take place from the other side to a greater extent than in motion or other sensations. He claimed that there is no evidence to prove the contrary. Dr. Mills's claim that the centre for cutaneous sensation is in the parietal lobe was at variance with all clinical facts.

Dr. Knapp related the results of autopsy in a child with athetosis from cerebral palsy. There was hydrocephalus, and basilar tubercular meningitis. The examination of the cord was negative. He believed that the view was generally held that the auditory centre resided in the temporal convolution. Except in rare bilateral cases, we cannot be certain until we have better means of testing the auditory fields. His views as to sensory representation in the cortex were in accordance with those of Dr. Dana. He referred to a case under his observation with anæsthesia and a lesion in the motor cortex. Ferrier's claim is disproved by the fact that there was anæsthesia in Dr. Mills's case, without any involvement of the gyrus fornicatus. He agreed with Dr. Dana that tactile sensibility was more represented back of the Rolandic fissure than anterior to it. Negatively, growths in the Rolandic region might exist without motor paralysis.

Dr. J. W. Putnam spoke of a case where, shortly after the removal of nasal polypi, there was gradual loss of memory, and at the eighth day, owing to the absence of sensory or motor disturbance, the diagnosis was made of abscess of the left frontal lobe. Trephined and removed three ounces of pus from frontal lobe. At the autopsy there was found an abscess of the corresponding frontal lobe. In another case with spastic condition of all four extremities, there was a glioma at the base, pushing the medulla to one side. In a child with athetosis involving the head as well as all the extremities, he found apparent absence of bridge of corpus callosum, and abscess in the apex of each temporal lobe. The case had been diagnosed by a good observer as absence or defect of the cerebellum.

Dr. Miles said he had seen a case where tactile sensibility was lost in the hand, after loss of brain-substance from the Rolandic region. This was the result of a fractured skull. He thought it would be difficult to locate the cortical areas in the negro by the same measurements in general use.

Dr. J. J. Putnam referred to a case where the accidental removal of part of the central convolution occurred during operation, and was followed by sensory disturbance.

Dr. Bremer said that he had seen a case in which an attempt was made to excise the wrist centre on right side for focal epilepsy. Neither paralysis nor other symptoms followed the operation. He considered the question un-

settled as to cortical motor and sensory areas. In the presence of spastic symptoms the question is not so much as to the location of the lesion in the subcortex, but the character of the tumor. The varying amount of blood-supply in a hemorrhagic cyst, probably gives rise to spastic symptoms.

Dr. Mills, in closing the discussion, said we are not yet in a position to settle this matter of sensory localization. He thought his case was not conclusive. His view is not that of Ferrier, Horsley, or Munk, but that we have a great sensory lobe, not the gyrus fornicatus or the hippocampal region, but it is an anatomically demarcated lobe. It may include the gyrus fornicatus, quadrate, and posterior parietal lobule. These regions are subdivisions of this sensory lobe, corresponding to subcutaneous muscular groups. Dr. Dana admits that in the cortex sensation has more representation than motion. This suggests one argument in settlement. Dana's cases must be satisfactorily explained. He could give thirty cases to Dana's one case, in substantiation of his view. There must be a sensory-motor association tract as well as a sensory-motor audition tract; cerebral paræsthesia comparable with paraphasia and paralexia. The convincing cases will be the bilateral. If this be true, then Dana has nothing to substantiate his claim. He suggested that sensation can be inhibited, as illustrated by hypnotism. Possibly we may explain the sensory symptoms by inhibition of a tumor in the motor region of the adjacent sensory region. He claimed that operative cases showed no objective sensory symptoms after the removal of large portions of the motor cortex. He was surprised to hear Knapp say that men who supported sensory localization did not support the views as to the centre for audition. As to myotomia and athetoid movements in his case, he was confident that there was no lesion in the capsule and no softening anterior to the retro-central fissure.

Paranoia Presenting Some Interesting Features.—This was the title of a paper read by Dr. C. Eugene Riggs, of St. Paul. The patient was a young man who, together with various other symptoms, had periods of double consciousness. The question would arise as to whether the patient's peculiar acts were prompted by the morbid egoism so common in paranoia, or were a manifestation not infrequently associated with epilepsy.

Dr. H. A. Tomlinson, of Philadelphia, had seen similar manifestations occurring in epileptics.

Friedreich's Disease, Its Relation to Conducting Paths in the Cord.—Dr. David Inglis, of Detroit, read a paper with the above title. He made a brief report of the symptoms presented by a case in which the essential features of the disease were manifest, and which corresponded accurately with Friedreich's own summary of the clinical characters of the disease, to wit, "Impairment in the co ordination and harmony of movements, developing gradually and spreading from the lower to the upper half of the body, and involving finally the organs of speech, sensibility, and the functions of the special senses and of the brain being intact," etc. The case is still under observation, but a consideration of the symptoms shown and of the pathological conditions found in recorded autopsies, leads to certain conclusions of interest in regard to conducting paths in the cord.

Ladame, in *Brain* (part lii.), has summarized the results of nine autopsies, to which must be added four autopsies during the past year. There is a very good agreement in them all upon the essential features of complete sclerosis of columns of Goll, marked sclerosis of the greater part of Burdach's column, of the direct cerebellar tract, and the vesicular column of Clarke. Less complete and not so uniformly found, is sclerosis of crossed pyramidal tracts. It becomes clear that all those tracts in the cord which degenerate upward, which are commonly looked upon as centripetal and as conveying sensory impulses, may be extensively destroyed, while yet the patient shows no impairment of the various forms of sensation.

We are driven to conclude that the function of the posterior columns and direct cerebellar is not to carry sensory impulses upward, but rather that they are the main channels for the conveyance of co-ordinated motor impulses downward. The facts of embryology confirm this theory; at the end of fœtal life, at a time when the crossed pyramidal tracts are undeveloped, the posterior and cerebellar tracts are complete—their function evidently begins at birth. When we remember that the new-born infant is not characterized by voluntary control of its muscles, not by accuracy of sense-perception, but by an extensive co-ordination of involuntary motor functions, the conclusion is easy that these tracts subserve these purposes.

The anatomical relations of these tracts with the midbrain and cerebellum are such that we must look upon them as the tracts for co-ordinated impulses from these centres to lower levels. The facts of Friedreich's ataxia compel this solution.

Election of Members.—The following-named gentlemen were elected to active membership: Dr. H. A. Tomlinson, of Philadelphia; Dr. Edward Cowles, of Somerville, Mass.; Dr. Henry H. Donaldson, of Worcester, Mass.; Dr. James Wright Putnam, of Buffalo, N. Y.; Dr. William Browning, of Brooklyn, N. Y.; Dr. Edward B. Angell, of Rochester, N. Y.; Dr. G. J. Preston, of Baltimore, Md.; Dr. Richard Dewey, of Kankakee, Ill.; Dr. Walter Channing, of Boston, Mass.

Papers Read by Title.—The following papers were read by title: "Syphilis of the Spinal Cord," by Dr. Philip Zenner, of Cincinnati; "Gunshot Wound of the Left Cuneus, with Complete Right Homonymous Hemianopsia," by Dr. J. T. Eskridge, of Denver; "The Virile Reflex in Relation to Clinical and Forensic Neurology," by Dr. C. H. Hughes, of St. Louis; "Facial Hemi-hypertrophy," by Dr. W. A. Hammond, of Washington; "A Case of Unilateral Paralysis of the Lips, Tongue, and Pharynx, with the Presentation of Specimens," by Dr. G. M. Hammond, of New York; "Fracture of the Eleventh Costal Spine, followed by Injury of the Spinal and Sympathetic Nerve-supply of the Bowel in the Region of the Ileo-cæcal Valve, Intestinal Hemorrhage and Death on the Seventh Day," by Dr. J. T. Eskridge, of Denver; "Some Suggestions Concerning the Etiology of General Paresis," by Dr. H. A. Tomlinson, of Philadelphia; "Statistical Notes on 232 Cases of General Paresis, with Special Reference to its Etiology," by Dr. H. M. Bannister; "The Mortality of Epilepsy in Asylums for the Insane," by Dr. Wooster.

Election of Officers.—The officers elected for the ensuing year were: *President*, Dr. C. L. Dana, of New York; *Vice-Presidents*, Dr. P. C. Knapp, of Boston, and Dr. E. N. Brush, of —— ; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York; *Councillors*, Dr. Wharton Sinkler, of Philadelphia, and Dr. E. D. Fisher, of New York.

In the evening a banquet was given by the Association, at which over thirty members were present.

AMERICAN GYNECOLOGICAL SOCIETY.

Sixteenth Annual Meeting, held at Washington, D.C., September 22, 23, and 24, 1891.

(Continued from p. 376.)

Third Day, Thursday, September 24th.

The Treatment of Extra-uterine Pregnancy by Morphine Injection.—Dr. F. Winckel, of Muenchen, Germany, sent the paper, which was read by Dr. Reeve, of Dayton. The author replied to a few theoretical objections which had been brought forward by E. Fraenkel and Künstner. His experience taught him that it was not necessary to do laparotomy the first few months of the extra-uterine pregnancy, that the injection of morphia into the amniotic sac was easier and better. Both ovaries and tubes

remained afterward, and even the contents of the tube might afterward become absorbed, so that the organ could perform its function. If the patient complained afterward of pain, laparotomy could then be performed. In the last nine months two cases had been cured by morphine injections into the amniotic sac. The patients had no pains nor aches afterward, one injection only was made, the tumor became smaller. This method especially recommended itself to the general practitioner unaccustomed to performing laparotomy. "More than one road leads to Rome."

Drs. Reeve, Fry, and Reamy expressed a preference for electricity where laparotomy was not to be resorted to. With Dr. Parvin, they regarded the testimony of Professor Winckel in favor of morphine injections as worthy of the most serious consideration.

The Immediate Closure of Laceration of the Cervix.—Dr. Cornelius Kollock, of South Carolina, gave the histories of three cases in which he had, being called in consultation, performed immediate repair of the cervix. In all of these cases there was hemorrhage, but he said he would do the operation in any case in which the tear was considerable. The hemorrhage in these cases ceased, and a perfect result followed. The immediate operation favored involution, and saved the patient the great suffering incident to neglected cases.

Drs. T. A. Emmet, R. B. Maury, and H. C. Coe would operate only where the tear was a cause of hemorrhage, while Dr. A. P. Dudley advocated immediate repair in all cases.

The Conservative Treatment of Pelvic Tumors and Diseases.—Dr. Eugene Gehrung, of St. Louis, attempted in this paper to show that certain conditions of the pelvic organs could be cured by conservative methods where laparotomy was now often resorted to. Of course reference was not made to pus sacs, and certain pathological conditions well known to demand the knife. He desired to show that in general, when organs (the uterine appendages) were not permitted to become incarcerated or strangulated, or when they were released from compression, the tendency of the tumor present to grow ceased partly or entirely. On the other hand, where there was firm pressure and conditions favoring irritation, goading the tissues into more rapid growth, laparotomy would in time be demanded. By relieving pressure (preventing formation of strong adhesions) and resorting to such conservative methods as might be indicated, symptomatic relief could be obtained and laparotomy avoided.

The Anatomical Relations of the Lacerated Perineum to the Mechanics of its Causation.—Dr. Edward Reynolds, of Boston, read the paper. It began with an account of some observations which he had been making during the last five years upon the shape and position of the rent in different cases, with an attempt to classify all perineal vaginal tears as modifications, to a greater or less extent, of one type form, which is substantially that described by Dr. Emmet in 1883, consisting of two lateral longitudinal tears of the vagina, joined at their lower extremities by a transverse tear, and connected with the external surface by a median tear of the tissues below the crescent. This tear, but slightly modified, is stated to be the most common form. That which has seemed to me the next in frequency is one of the lateral tears, half the crescent, and the external tear. The crescent alone is not infrequent. I have also seen one lateral tear extend down through the skin by the side of the anus without passing toward the median line. It seems to me that all lesser variations can be arranged under these four varieties. I then proceed to attempt to explain the determination of the rent along this line in all cases by reference to the pelvic anatomy, dividing the tissues of the pelvic floor into two layers, of which the superior consists of the recto vesical and obturator-vesical fascia, with the contained coccygeal muscles, reinforced anteriorly by the triangular ligament; while the inferior consists of the two layers of the superficial fascia, the compressor urethræ, superficial transverse, and sphincter ani muscles. My view is that, when the head is forced through the pelvis with a degree of speed which is too great for the elasticity of the vagina, and consequently produces an intra-vaginal tear, the point of separation is likely to be that at which the strong lateral portions of the superior fascia are attached to the lateral edges of the vagina; this union of three bands of different tensile strength determining the situation of the two longitudinal rents. The crescentic tranverse tear which unites the lower extremities of the longitudinal lacerations is accounted for in the following manner: Owing to the obliquity between the superior layer of the pelvic support and the axis of the vagina, the posterior edge of the vaginal opening in this fascia is carried downward and forward as the head traverses the curved pelvic canal, while its anterior edge is raised and compressed against the pubes, so that the posterior half of the fascia is put upon the stretch, while its anterior portion is relaxed. The action of this upper layer as a whole may be summarized as that of its posterior portion, which resists the downward and forward motion of the perineal body and fourchette. The inferior layer is strengthened in its anterior part by the superficial fascia, which is stated by Savage to be a somewhat firm, fibrous sheet which is especially strong where it is reflected from the transverse muscles. The posterior half is composed of little but skin, sphincter-ani muscle, and peri-rectal fat; so that the action of this lower layer is essentially but little modified from that of its anterior half. The efficient posterior half of the superior fascia is joined to the efficient anterior half of the superficial layer only by the small amount of indifferent connective tissue which binds them together in the perineal body. This attachment furnishes a weak line of cleavage which runs transversely between the inferior ends of the longitudinal tear. When such a separation has occurred the edge of the superior fascia retracts, and is no longer of importance. The head is then restrained only by a thin hood of superficial tissues, which parts along the median line in accordance with the classical explanation given by Savage. Those tears in which the transverse element is most strongly marked have seemed to me to follow prolonged second stages; those in which the longitudinal element is most developed have been generally the result of very rapid labors with powerful expulsive forces. I have had prepared a number of large diagrams, illustrating the lines in which the mechanical action of the various layers comes into play, and a set of diagrammatic views of the more common varieties of laceration, which were drawn from life, some of which exhibit well the form of laceration which, after the muscular retraction of the tissues sets in, bears an extremely close resemblance to the classical longitudinal laceration in the median line—which last tear I have of late years failed to find.

The Electrical Treatment of Uterine Fibromatæ in England.—Dr. George Keith, of Brooklyn, based this paper upon a study of the subject made in England. He had opportunity of examining the first one hundred cases treated by Dr. Keith and Dr. Skene Keith, and of seeing the treatment and results. He had compared these results with those of hysterectomy and removal of the ovaries, by other surgeons in Great Britain, and the conclusions that he had drawn were vastly in favor of the electrical treatment. He had become convinced that there was room for all methods of treatment of the uterine fibromata, that no one method should be practised to the exclusion of others. This was also the opinion entertained by Dr. Keith. It appears to have gone abroad that he had abandoned hysterectomy since he had taken up treatment by electricity, but this was a great mistake. He still operated in suitable cases; to the author's knowledge he had operated three times the last six months, yet he believed that electricity would cure the vast majority of cases, and this would guard against

the necessity for hysterectomy. There was no doubt but what hysterectomy was frequently performed to remove a tumor which was giving little or no trouble. The advantage of electricity after Apostoli's method were the almost complete freedom from danger and the maintenance of the characteristics of the sex. But the method was yet in its infancy, and the results should be compared with the early results of hysterectomy, which gave a mortality of fifty per cent. Even the fractional death-rate from electricity would, he believed, disappear by the time that method of treatment had been practised as long as hysterectomy. He believed there were not many women who had suffered from an active uterine fibroid who would not be satisfied to be symptomatically cured by electricity, although an inert mass remain in the abdomen, if the risks of an operation were fairly put before them. But the mortality from removal of the ovaries alone should be very small, and the woman should be allowed to choose between this treatment and that by electricity. The electrical treatment took three months, but while it was going on the patient could attend to her duties and enjoy life to the fullest extent on non-treatment days.

Drs. Ford, A. P. Dudley, and A. J. C. Skene, spoke of the value of the electrical treatment, Dr. Dudley having ceased to be a sceptic only after a visit to Apostoli the present year. Dr. Sutton, of Pittsburg, called this treatment "rot."

Laparotomy in Trendelenburg's Posture, with Exhibition of a New Operating-table.—Dr. Clement Cleveland, of New York, formulated the advantages of operating on the abdomen with the pelvis elevated as in Trendelenburg's posture, the intestines descending toward the diaphragm, and exhibited a table which he had devised, and which was composed entirely of galvanized iron.

Drs. Goodell, Edebohls, and Sutton gave their testimony as to the advantages of this posture, and Dr. Edebohls mentioned the fact that the table which he had constructed was adapted to use in general gynecological surgery as well as in laparotomy in Trendelenburg's posture.

Diabetes Mellitus Gravidarum.—Dr. Henry D. Fry, of Washington, read a paper on this subject. Physiological glycosuria, and different forms of diabetes, must not be confounded with diabetes mellitus gravidarum. Under the title of "puerperal diabetes" Mathews Duncan had reported several cases of his own, and as many others as he was able to collect, and the report comprised twenty-two pregnancies in fifteen women. One case had come under the observation of the reader. In the first pregnancy there was normal labor. Diabetes developed about the fifth month of second pregnancy. Death of child and premature labor at seventh month. The mother died five days after labor.

Judged by the paucity of the literature on the subject, it might be inferred that diabetes occurring during the child-bearing period was an extremely rare complication. The author thought, however, that it was not so uncommon as it was unrecognized. That peculiar condition of the pregnant woman which was responsible for the development of the disease in one case, was likewise the factor in adding malignancy to a pre-existing mild attack in another. To aid in recognizing the affection, glycosuria should be suspected and the urine examined for sugar in all cases of pregnancy presenting obscure symptoms—weakness, emaciation, short breathing, etc. It was a good rule to suspect this disease whenever a child was born dead without other apparent cause. Syphilitic poison was no more certain to destroy fœtal life than the diabetic condition. Diabetes might develop at the beginning of gestation, but was usually deferred to about the period of quickening. The disease was less responsive to treatment than under other circumstances. But if it did not terminate fatally before confinement there was more hope. Subsequent pregnancy might start it to renewed activity.

Enough cases had been reported to confirm the statement that diabetes occurring in the child-bearing woman might assume the intermittent form, notwithstanding the admitted rarity of that type of the disease under other circumstances. Death of the fœtus generally occurred about the seventh month, but expulsion might not take place for two months afterward. Excessive development of the child had been mentioned in several cases. Should a woman marry who is suffering from diabetes? From the evidence given, the reply must be in the negative.

Our present knowledge of the subject did not enable us to reply to the question, Should premature labor be induced? He would say, however, that when the symptoms were acute one would be justified in inducing premature labor, which should be done at the earliest time the child was viable.

Officers.—The election of officers resulted in the choice of the following: *President*, Dr. John Byrne, of Brooklyn; *Vice-Presidents*, Drs. R. B. Maury, of Memphis, and Cornelius Kollock, of Cheraw, S. C.; *Secretary*, Dr. Henry C. Coe, of New York. Place of meeting, 1892, Brooklyn, N. Y.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at the Shoreham Hotel, Washington, D.C., September 22, 23, 24, and 25, 1891.

(Continued from p. 377.)

Second Day, Wednesday, September 23d.

The Treatment of Tuberculosis was discussed in a paper by Dr. Fox, of New York, who considered first the local and then the constitutional management of cases. In treating lupus three objects are to be aimed at: 1, The removal of the disease; 2, causing as little pain as possible; 3, producing the least amount of disfigurement. The oldest method of effecting the first was by the knife, this to be considered in no wise the preferable way. Cautery is condemned as painful and disfiguring and inferior to other methods. The flat electrode has given good results in some instances, but it is slow. The curette is of itself insufficient to effect a cure. Scarification has had too much said in its favor. The hypothetical fear that it may set free the bacilli, and allow them to penetrate the system and cause pulmonary tuberculosis, is not a serious objection, but it is only in the ulcerating lupus of the nose that the method appears to the reader superior. In one case fuchsine after scarification appeared to act extremely well. It is believed that there really exists such a thing as scrofula which renders or leaves the subject liable to tuberculous disease, and while cod-liver oil has no beneficial effect in lupus or skin tuberculosis, it has decided worth in this condition. The iodide of starch is highly praised as a reconstructive agent in strumous disease. It should be freshly prepared, by adding twenty-four grains of iodine to an ounce of starch.

Of specific methods in cutaneous tuberculosis, Koch's is the only one worthy of attention. In general the results had been negative, but in some cases the lupus tissue beneath the surface seemed to have been softened by the lymph so that the beneficial results appeared subsequently after other plans of treatment had been instituted. Dr. Piffard said he had published his opinions on the infectious nature of tuberculosis as early as 1877. He still holds that lupus erythematosus is of probable bacillary origin, and is entitled to the name lupus just as much as is lupus vulgaris, cold dermic abscess, or phlegmonous scrofulide, and rodent ulcer he looks upon in the same light, and believes that bacilli will be found in them. An etiological designation would be better than to continue calling these diseases lupus and scrofulide. As to the treatment of lupus the views now held only emphasize those held many years ago. There is only one rational method, and that is to remove the disease by excision

when this can be readily done. Cosmetic results are not of as much importance as is the total elimination of the disease. The bacillus lies deeper than cautery penetrates, so combined scraping and cautery are advised, the latter strong enough to destroy thoroughly. There is only one objection to arsenic, and that is its painfulness. The chloride of zinc combines a disinfectant with the cautery effect.

Dr. Allen spoke of the advantages of scarification and the pyrogallol and mercurial treatment under which he had recently had some successes.

Dr. Zeisler extols the galvano-cautery used in various ways. The skin can be congealed and rendered painless by methylene chloride. He also defended the nitrate-of-silver stick so much used in Vienna. Koch's lymph had only given negative results in his hands.

Dr. Bronson thought the distinctive names should be retained. He thought the dental burr rendered the silver stick unnecessary.

Dr. Hyde was still of his previous opinion, that in the majority of cases of lupus there was no tuberculosis history in the family. He does not approve of scarification. After rhigolene spray he employs the cautery and nitrate-of-silver stick. He thought the time might come when he would find that there was something in the Koch lymph after all.

Dr. Duhring would not discard the old names. He has not noted either local or general tuberculosis in connection with lupus cases. Pyrogallol is well thought of, but he employs it made into a paste with resin cerate, ʒ iij.; soap plaster, ʒ j.; pyrogallol, q. s. This is to be applied continuously, and the beneficial results are more accurately and more quickly obtained. He has seen no favorable results from tuberculin, except in one case, where the tissues had become softened after its use.

Dr. Morrow thought etiological names would be better. Treatment is much a matter of choice. The scarification method which Dr. Fox condemns has proven successful in his hands. There is little basis for the fear expressed regarding auto-infection, and if this danger were really present, igneous scarification would do away with it. For scattered nodules he employs punctate scarification with an instrument at a white heat. The possibilities of plastic surgery will make excision a favorite method.

Dr. Robinson said it was impossible to have an etiological classification at present. We are still far from the goal in therapeutics. It must be reached by making the soil unfavorable for the development of the disease, or destroy it *in situ* without resort to surgical means.

Dr. Klotz said it was too sweeping a statement that wherever bacilli of tuberculosis were found we have a tuberculous disease.

Dr. Bulkley recommends phosphorus internally up to the point of tolerance. Pyrogallol he uses as a powder applied locally.

Dr. Sherwell thought it still unproven that the bacilli were the cause and not the effect. Each case of lupus must have its especial method of treatment.

Dr. White thought we might still find extra human modes of infection. He still uses parasiticide remedies.

Third Day, Thursday, September 25th.

Notes on a Visit to the Leper Hospital at San Remo, Italy.—Dr. Duhring, of Philadelphia, having recently paid a visit to the San Remo Leper Institute, described the appearances of a number of cases examined. No segregation or restraint is practised. It is believed that many lepers exist outside of institutions, especially in Southern Italy.

Notes on Skin Grafting.—Dr. Morrow read a paper on the transplantation of skin, and exhibited a patient upon whom he had operated for an epithelioma. The peculiarity of the operation consists in the absolute accuracy with which a piece of skin removed by means of the cutaneous punch is inserted into a raw surface made by the same instrument.

Report of a case was read in which scar-tissue upon the scalp was removed and pieces of hair-bearing skin, taken from the scalp of another person, were inserted with partial success. The integrity of the hair-bearing structures can be maintained if the grafts are taken deeply enough. The method is especially applicable after operation upon the face for cancer, warts, moles, scars, etc. The dangers of recurrence after operation for epithelioma are thus thought to be decreased.

Dr. Shepherd thought the principal point in any form of grafting was to make it aseptic. The skin from amputated limbs and from the dead body had often been employed by himself.

The Treatment of Alopecia Areata was the next paper, by Dr. Morrow, of New York. In one case of universal alopecia persisting for many months, after an attack of measles, there was a renewed activity in the growth of hair. At another time marked improvement took place upon the scalp after a sunburn of this region.

The clinical fact of concomitant vitiligo was referred to and illustrated by a case. The parasitic theory is regarded as the only one consistent with our present knowledge of alopecia in the majority of cases. Treatment should be based on the indications presented by each individual case. Stimulation and irritation in some form are called for in almost all instances. It is not deemed necessary that the stimulant should be parasiticide at the same time. In the simpler cases clipping the hair and epilation surrounding the patch is advisable. Then chrysarobin, five to ten per cent., and salicylic acid, two to five per cent., in traumaticin are to be applied. Massage, stimulating oil, and the shampoo are adjuvant means. Acetic acid is well thought of. Pilocarpin and electricity have not been followed by success in the reader's hands.

A Therapeutic Note on Alopecia Areata was read by Dr. Bulkley, of New York. Pure carbolic acid of a ninety-five per cent. solution is the drug which has given him good results for several years. It is not to be applied to too large areas at a time. There is slight pain from it, but patients do not object to subsequent applications. The reader had only employed this remedy upon the scalp. An interval of one or two weeks is often advisable. The reader does not believe in the parasitic origin of the disease, and uses the acid not as a parasiticide but as a stimulant.

Dr. Zeisler thought it unfortunate that one not believing in the parasitic theory should employ such a recognized parasiticide. He has employed salt as a stimulant.

Dr. Corlett has seen no benefit from acetic acid.

Dr. Fox spoke well of this remedy. He believes that a general constitutional condition underlies the disease. A daily plunge-bath will prove as efficacious as any local applications.

Dr. Duhring has always held to the view that the disease is not contagious. Arsenic he believes of much value in the treatment of the disease, and superior to all local methods combined.

Dr. White thought there was no positive proof on which to base an opinion as to the etiology. He described an epidemic in an institution which simulated alopecia areata more closely than any other disease he knew of, and which was evidently not tricaphytosis. He used by preference croton-oil, half a drachm, and oil of turpentine, eight ounces, rubbed daily. If this does not succeed he finds other remedies fail as well.

Dr. Stelwagon has never seen instances of infection or contagiousness. He employs both internal and external treatment.

Dr. Hyde thinks the time will come when we will regard alopecia areata as simply a symptom due to a variety of causes. Some instances we must look upon as neurotic. The element of age must be considered in the prognosis. In after life the prognosis is bad.

Dr. Sherwell believes in the neurotic character of true alopecia.

Dr. Grindon has never seen any reason in his practice for basing a positive opinion as to its parasitic nature.

Dr. Greenough had used carbolic acid in ointment for many years.

Dr. Morrow believes a certain contingent of cases are neurotic.

Dr. Allen had long believed in the parasitic nature of ordinary alopecia areata. Two cases in the same family in his experience had pointed to contagion. Internal remedies may render the soil unsuitable for the development of the parasite, and it is likely that some remedies act in this way. He had found naphthol a remedy of value for external application.

Dr. Bulkley insists upon a light application at first to benumb the sensibility, then to brush it in the acid very thoroughly. He gives strychnia and phosphoric acid internally, and increases nutrition in every way possible.

Dr. Bowen had examined the cases spoken of by Dr. White, but while no parasite was found, tricophytosis was excluded.

Xeroderma Pigmentosum was the title of a paper read by Dr. Taylor in description of two cases of Dr. Brayton, of Indianapolis, illustrated by a painting. The disease began at about the age of six and eight months respectively. The family history shows only the two elder children affected. One child died at the age of two, the second is now fifteen. One lesion at the ala nasi the writer fears may become cancerous, if it is not already so.

Pruritus was the next paper, by Dr. Bronson, of New York. Molecular changes within the sensory apparatus constituting pruritus should be recognized as a disease. Cutaneous hyperæsthesia is almost always present. Many cases must be explained by reflex irritation. Hairy parts are peculiarly liable to pruritus. Spastic muscular contraction affecting the peripheral nerves should explain pruritus as much as their contraction about the veins in the skin are the indirect cause of the production of wheals in urticaria.

In conclusion, it is not always easy to distinguish between the primary and secondary features of pruritus. There is a motor and a sensory disturbance, the sensory predominating.

Prurigo would be a simple pruritus had not the scratching produced papules and other lesions. So in pruritus hiemalis the secondary effects are subsequent to the irritation from scratching. The seat of the pruritus is in the epidermis, and is dynamic, though the original seat may be central. Dr. Morrow has observed that long before any visible lesion was present in lepra, there was, perhaps for months, a decided pruritus. Here the changes are in the nerve-trunks and not in the cutaneous distribution of nerves.

Diseases of the Skin Associated with Derangements of the Nervous System was the next paper, by Dr. Corlett, of Cleveland, based upon several clinical cases of neurotic origin. Two cases resembled lupus erythematosus of the face, and one vitiligo, in association with ulcerative and other lesions. They occurred, with one exception, in young women. In two, local irritation appeared to be due to errors of refraction. When these were corrected the eruptions disappeared. In the third there was an hereditary nerve degenerative process.

Dr. Bronson thought we might classify these cases without reference to the nerve element. The first case looked from the photograph much like a lupus erythematosus.

Dr. Fox thought from the distribution and appearance of the lesions in one case that it was an erythematous lupus. The element of itching mentioned by the reader would not be sufficient to exclude this disease. We know that there are neurotic skin diseases, but, as a rule, the nerve disturbances must be separated from the skin lesions.

Dr. Corlett said he had at first regarded two of the cases as lupus erythematosus, but they had not given way to the usual treatment, yet one had been cured after the nerve-centres had been given proper rest.

Chronic Ringworm of the Scalp.—Dr. Duhring, of Philadelphia, based his paper on his experience in an epidemic which occurred in an institution for boys. Ringworm had been prevalent for years, and at the time in point there were forty-six cases discovered. In the selection of remedies stronger ones were employed in those of dark complexion than in blondes. Depilation was given up in most cases as impracticable. Soft soap and sulphur were employed to cleanse the surface. As to parasiticides, carbolic ointment proved less curative than some other drugs. Tar was not efficacious. Iodine likewise. Oleate of copper was abandoned. Mercurials were disappointing. Calomel, however, subdued inflammation of the scalp. Croton-oil was found especially useful, followed by mild parasiticides. In no case was eczema produced by the disease nor by the remedies. Sulphur and chrysarobin were used with much benefit. The first in strength of from one to three drachms to the ounce; the second often supplementing it. Chrysarobin was found to be the most valuable drug employed. The strength varied from fifteen grains to two drachms to the ounce. The smallest possible quantity should be used, and be well rubbed in, the strength being gradually increased.

Dr. Fox prefers solution of the drug in traumaticin to greasy ointments.

Dr. Zeisler spoke of pyrogallol in solution of ether and alcohol, ten per cent., which gave him uniformly good results.

Dr. Grindon had tried the cataphoric use of bichloride, but saw no difference between the drug thus applied and used simply as a wash.

Dr. White uses a combination of sulphur, carbolic acid, and naphthol for out patients, and never chrysarobin or pyrogallol in these patients, on account of its danger.

Dr. Stelwagon agreed with Dr. White. He regarded tar as a rapidly acting and effective drug.

Dr. Klotz uses chrysarobin in chloroform solution.

Dr. Sherwell employs oily substances, tar, and mercurials.

Dr. Wigglesworth objects to a treatment by ointments, but thought some of the oleates would do well, excepting the oleate of copper, with which he had not had good results.

Dr. Allen referred to an epidemic among the girls in an asylum which he had been asked to take charge of. He had spoken of the value of chrysarobin in tricophytosis in discussing the papers on alopecia in the morning session. This drug he had employed extensively in the institution, but had used it in solution. He agreed with Dr. Fox that ointments were uncleanly.

Epilation.—Dr. Zeisler, of Chicago, considered the range of usefulness of epilation, as a dermo-therapeutic measure. This method of treating sycosis is only about thirty years old. He prefers the epilating forceps made in this country to those of Vienna. By epilation we remove the parasites, which are in the hair-shaft, do away with the irritant tissues to the surrounding hair itself, and open the deeper parts to the action of parasiticides. A crusade has been begun against the process of Unna and others who claim that in sycosis shaving is sufficient; but the reader would rather give up all adjuvant treatment than his epilation forceps. In favus epilation is indispensable, though tedious, and must be persisted with till a cure is effected. In eczema sycosiforme epilation gives markedly good results. In alopecia areata, in eight cases, cure was effected in from six to eight weeks, by epilation combined with pyrogallol, and spreading did not occur.

Dr. Fox agreed as to the great usefulness of epilation, but thinks some chronic cases will get more benefit from proper hygienic surroundings than from any local measures.

Dr. Klotz thought epilation important, but sycosis can be cured without it by mild naphthol, sulphur, and zinc ointment. In favus total epilation of the whole scalp is often requisite.

Dr. Duhring had found the pain from epilation so severe that patients would not stand it. In marked cases of alopecia areata there are no diseased hairs left to epilate.

Dr. Morrow took exception to this view.

Dr. Stelwagon has not found epilation essential in sycosis. He employs Vlemink's solution, one part to ten or twelve to begin with, and the strength gradually increased.

Dr. Hyde regards epilation of importance, except in sycosis of the upper lip.

Dr. Allen had usually found the hairs at the periphery of alopecia patches loose, and thought it was a generally accepted fact that they were so.

Dr. Duhring said he meant to refer only to the chronic cases of alopecia as those in which the hair at the periphery was fixed.

Fourth Day, Friday, September 25th.

Molluscum Contagiosum.—A paper upon this subject, by Dr. Graham, of Toronto, showed the contagious nature of the disease from clinical data furnished by an outbreak in a nursery. A micrococcus was separated, cultivated, and inoculated, but with only negative results. It was probably the micrococcus epidermicus albus described by Professor Welsh. The molluscum bodies were carefully studied by Dr. McAdam, in connection with the histology of molluscum tumors. The tumors were found to take their origin in the stratum mucosum, and to have a downward growth. Molluscum corpuscles are in nowise to be considered as themselves the bearers of contagion unless they carry micro-organisms.

Dr. Bowen said there was no longer a question in his mind that the growth was not of sebaceous origin, as some still claimed it to be. He regarded it as undoubtedly contagious.

Dr. Allen referred to clinical facts proving its contagious nature. He thought it probable that the molluscum bodies were in some way the bearers of infection.

Dr. White said that granting its contagious nature we must not wrongly judge the molluscum bodies. He could not regard them as the contagious elements.

Dr. Sherwell spoke of Dr. Piffard's refraction experiments to prove the epithelial nature of the bodies.

Dr. Graham said he thought the amyloid degeneration showed them to be epithelial and not coccidial.

Pemphigus Vegetans.—A note relative to this disease was read by Dr. Hyde, of Chicago, describing a case beginning in the ano-genital region of a female patient, and being mistaken by those who first saw the case for one of condylomata of venereal origin. Patches developed upon the neck, back, and elsewhere, with formation of bullæ upon circumscribed areas of redness. Convalescence is now going on and is promising, but a good prognosis cannot be given. Cultures were made of the bullæ contents, and a micro-organism was isolated, but could not be regarded as specific. Since Croker's review of the subject Neumann has made a valuable contribution. The present is the first case recorded in this country. It is a unique disorder, pointing to a morbid condition of the nerve-centres; but while we are not justified in giving a pathological designation the name pemphigus marginatus is suggested.

Dr. Duhring stated that from observing this case there was only one condition to exclude, and that was syphilis. The name he thinks a good one.

Dr. Bowen had seen one of Dr. Neumann's cases in Vienna, and Dr. Hyde's description tallied very closely with this. He does not think the term pemphigus gives much idea of the condition.

Dr. Sherwell spoke of a somewhat analogous condition in which ovariotomy had been followed by a cure.

Dr. Graham referred to a case resembling this one, but with more severe mouth symptoms. Arsenic in large doses was followed by almost complete recovery. The patient is still alive. There were no vegetations, but the marginate appearance was striking.

Mycosis Fungoides, with Report of two Cases, was the subject of the paper by Dr. Stelwagon, of Philadelphia. One case presented at first a fungoid or mushroom-like tumor over the region at the base of the thumb. Other tumors became scattered over the body and a redness simulating an eczema, with occasional erysipelas-like attacks followed. In the second case there were at first lesions, which came and went like urticaria, then tumors appeared over various regions of the body, in size from a pea to a small cherry. These soon became much larger, and some reached the size of an orange. There were also eczema-like outbreaks. Both cases resulted fatally. Histological examination showed a growth resembling round celled sarcoma. Bacteriological examination showed similar micro-organisms to those found by other observers in this condition. Sixteen animals were inoculated. Results negative. Post-mortem changes were found to be similar to those seen in previously reported cases. The writer classifies the condition with the specific granulomata.

Dr. Hyde spoke of the spots which precede the characteristic tumors and other features of the disease.

Dr. Hartzell agreed that this form of tumor must be classed as specific granuloma.

Dr. Bowen said it was a matter of choice whether the massed cells were denominated lymphoma, sarcoma, or granuloma.

Dr. Duhring thought it bore so much resemblance to lepra, syphilis, and glanders that it was in all probability an infectious disease, but nothing till now has shown it to be either contagious or infectious.

Dr. Fox spoke of a case he had observed, and of the development of a typical case of sarcoma in the person of a woman who occupied the adjoining bed in the ward. Another case resulted fatally within six or seven months.

Dr. Stelwagon said literature showed nearly a hundred reported cases.

Lymphangioma Circumscriptum.—Dr. Hartzell, of Philadelphia, reported a case of this rare disease, and reviewed the eight cases previously put on record, one only having been previously observed in this country. Treatment by cauterization to destroy the vessels thoroughly is the only plan recommended.

Dr. Stelwagon spoke of the confluent nature of the superficial vesicles.

Dr. Bowen spoke of the presence of angiomatous dilatations as well as the lymphangiomatous.

Carbuncle.—Dr. Klotz, of New York, described a peculiar case of carbuncle, implicating the back of the head. There was absence of pain and surrounding inflammation. The region was unusual, and there was considerable parenchymatous bleeding; mycosis fungoides, kerion, and other conditions were suggested by the appearances before the proper diagnosis was made of diffuse carbunculous inflammation of unusually large size. The writer approves of the name carbunculous dermatitis for certain similar cases.

Dr. Bowen spoke, in this connection, of the subcutaneous fat columns, or prolongations, described by Dr. Warren, of Boston, which he thought had not yet received the recognition which their importance warranted.

Erythema and Nævus Nuchæ was the title of a paper by Dr. Allen, of New York, whose observations had led him to consider nævus, or birth-mark, in this region of quite frequent occurrence. Erythema, occupying the central portion of the back of the neck, and extending an inch or more into the hairy scalp, appeared to be present in about seven per cent. of healthy people. In syphilitics this proportion is increased so greatly that the writer

thought it might prove a sign of some value in the diagnosis of this disease.

Lichen Ruber was considered by Dr. Grindon in a paper and report of a case. The eruption was attended with most severe pruritus, exacerbations occurred in cool weather, and the eruption almost disappeared in the warm season. The course was very chronic, almost complete cure apparently took place after a surgical injury. The papules were distributed over the whole surface of the body, the extremities being the parts last to be invaded. The hair and nails finally became implicated late in the disease.

Dr. Zeisler regretted the still great confusion surrounding the lichen group. The description corresponded in many particulars with his own case of lichen planus.

Dr. Sherwell would regard it from the description as lichen planus rather than lichen ruber.

Dr. White said the case did not meet his view of lichen ruber, nor yet wholly of lichen planus.

Dr. Hyde said he very often saw the typical polygonal outline and umbilication which Dr. Zeisler had failed to find as a rule.

Dr. Duhring thought the case one of lichen planus of divergent type. The polygonal shape and umbilication is often absent, still it is probably more often seen here than in Europe.

Dr. Grindon asked if anyone present had seen a case of lichen planus involving the nails, or beginning on the face and remaining localized there for years.

There was no response.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirteenth Annual Congress, held at the Arlington Hotel, Washington, D.C., September 22, 23, and 24, 1891.

(Continued from page 379)

Third Day, Thursday, September 24th.

The Symptoms and Pathological Changes in the Upper Air-Passages in Influenza.—A discussion on this topic was opened by Dr. J. Solis-Cohen, of Philadelphia. He had seen during the recent epidemics nearly all the common inflammatory states usually met with, but the most characteristic condition was that of lymphoid œdema. This had occurred in various sites, even in the glottis, producing death from spasm. Purpuric spots existed in the trachea in some instances. The process seemed to run to the various nasal sinuses and thus led to cerebral mischief. Otitis media was common, also hemorrhage and abscess of the larynx. Paralysis of the throat muscles had followed as in diphtheria. The etiology was obscure. General telluric disturbances had occurred at about the time of the epidemics. The symptoms were not at all characteristic. In addition to those following the various local affections there was a peculiar nervous prostration coming on very suddenly. Catarrh had seemed to affect about one-fourth of all the cases, while the rest suffered from pulmonary nervous and gastric symptoms. If the outside areas where the lymphatic œdema existed were incised there was a lymphoid leakage rather than one of sero-pus. The congestion of the catarrhal areas seemed to be passive rather than active. There was undoubtedly a vaso-motor paresis of both the blood- and lymph-vessels.

Dr. Cohen narrated two interesting cases. A man aged eighty had an epithelioma of the palate which was treated with partial success. He suffered severely from the influenza, but after recovery from the latter the epitheliomatous condition disappeared also, and to-day the patient is perfectly well. A woman fifty years of age had tuberculosis of both larynx and lungs with profuse expectoration. She caught the influenza and not only recovered therefrom, but her throat and chest symptoms also disappeared and to-day she is a well woman.

Dr. Shurley, of Detroit, called attention to the antagonism existing between different diseases, as tuberculosis and erysipelas; also the correspondence in mode of onset of influenza to cerebro-spinal meningitis. An alkaloid had been extracted from tubercular sputa which by inoculation caused a lymphoid œdema without pus, as in the glandular variety of diphtheria.

Dr. Wright, of Brooklyn, noted an absence of local lesion in the second epidemic, but the prominence of the nervous depression and prostration. The middle ear had been frequently affected.

Dr. Asch, of New York, had found tonsillitis with great depression the most common feature

Dr. Casselberry, of Chicago, had found a most violent catarrh in all the upper air-passages, but no specific lesion. It began above and ran down to the pleura and lungs.

Dr. S. Solis-Cohen, of Philadelphia, had found more affections of the upper air-tract in private than in institution cases. After otitis media seemed to be the only lesion.

Dr. Roe, of Rochester, had found that those with a previous hypertrophic rhinitis suffered especially from head symptoms, those with chronic pharyngitis from throat symptoms. The cause of the œdema was a vaso-motor paresis associated with cardiac weakness. He had not regarded it so much as an inflammatory affection. Cardiac stimulants had been of the greatest service.

Dr. Langmaid, of Boston, had had one case of œdema of the glottis from the influenza, but the most prominent feature in the disease as occurring in Boston had been otitis media. In general there had been but little tonsillar engorgement. Lower down there was a circumscribed broncho-pneumonia. This latter generally cleared up, but sometimes left a lasting hepatization owing to the cellular infiltration.

Dr. Jarvis, of New York, thought that patients with a previous pathological condition of the septum had been more liable to be attacked than those with other forms of spinal disease.

Dr. Robinson, of New York, had found the middle ear to be frequently involved, but the appearance of the organ did not at all correspond to the severity of the subjective symptoms. The tube was pervious and the drum membrane apparently normal. Tinnitus was greatly complained of, with a dull heavy feeling in the ear, and the sense of the presence of a foreign body. The cases were generally more severe on one side than on the other. did not go on to suppuration, and were very obstinate.

Dr. Glasgow, of St. Louis, had seen considerable suppuration of the antrum as a sequela. The exudation in the influenza seemed to be always purulent, whether on the mucous or serous membranes, or in the brain. Catarrhal disease was modified during the attack, but returned as soon as the epidemic passed away. In fatal cases there had been found a softening of all the viscera, especially of the cardiac fibre.

Useful Deductions Derived from the Study of a Case of Cicatricial Contraction of the Larynx, Possessing Unusual Clinical Features, with Exhibition of Specimen.—Dr. W. C. Jarvis, of New York, read a paper with this title. His patient was a man aged sixty, who had a specific lesion forty years before. For only some three years before his death he began to complain of headache, vertigo, and suffocative attacks, especially severe at night. His nasal septum was perforated, and from the nose the disease had travelled down to the larynx. The sites of invasion all showed much scar-tissue. The epiglottis showed only a cartilaginous remnant. The upper laryngeal aperture consisted only of a small circular opening, yet a fair phonation led to the belief that the vocal cords were still intact. The suffocative attacks were probably due to the inspiration of food and liquids, extra laryngeal mucous, subacute catarrhal congestion, and there was frequent inspiratory spasm. Palliative measures, consisting of local lubricant applications, gave some relief. Iodide of potash greatly benefited the asth-

matic attacks, as it was well borne. But tracheotomy was finally advised, as in spite of all that was done the patient grew worse. He finally died of enteritis without having had the operation performed. The peculiar features of the case were his long and, for a considerable length of time, comfortable sickness. Intubation to dilate the stricture was not permissible, as it was impossible to get at the latter, and the least instrumental irritation of the larynx caused a spasm. Dr. Jarvis believed that if the nasal lesion had been properly treated at the first, the lower affection would not have occurred. The relief from the iodide was ascribed to its effect on the pulmonary emphysema which the patient had, though the asthma was probably due in part to coexistent syphilis of the lungs.

The specimen was exhibited, and the stricture scarcely afforded entrance to an ordinary match.

Dr. J. Solis-Cohen thought that a normal glottis would be found in the specimen if the stricture was cut into.

Dr. Mackenzie, of Baltimore, related a somewhat similar case of a young man, aged twenty, who suffered severely from inspiratory dyspnœa due to bilateral abductor paralysis. He was immediately tracheotomized, but the relief was slight. He steadily grew worse and died in two or three days. Post-mortem a small gumma was found in one apex. Both recurrent nerves were encased in a mass of cicatrized and enlarged glands, while the individual fibres had undergone a fatty and granule degeneration. There was at the bifurcation of the trachea a stricture so narrow as scarcely to admit a fine probe. The patient had been on large doses of iodide, and was "killed by his cure," as the cicatrization of the specific ulcers had led to the stricture. He had become infected from the gumma in the apex. This local confinement of syphilis to the respiratory tract is not uncommon.

Dr Asch thought that the use of either Schroetter's or O'Dwyer's tubes might have relieved Dr. Jarvis's case.

Dr. Casselberry, of Chicago, thought there was great danger in palliative measures, as any chilling or nervous influence might provoke a fatal spasm in these cases. Tubage is dangerous. Tracheotomy should first be done and may be supplemented by dilatation and the iodide.

Dr. Sajous, of Philadelphia, thought there was a danger often overlooked in the use of the iodide itself. In too large doses it may cause laryngeal œdema, especially where we have manifestations of kidney disease. Tracheotomy tubes should always be at hand.

Dr. S. Solis-Cohen, of Philadelphia, did not see how it was possible for œdema to occur in a cicatricial mass. He had noticed that a very small passage would supply enough air.

A Case of Epithelioma of the Larynx.—This was the title of a paper read by Dr. Morris J. Asch, of New York. The case was one of intrinsic cancer in a man, seventy years of age, who for a long time suffered only from hoarseness. The site of the growth seemed to be the left ventricular band. The left ary-epiglottidean fold was normal. The sub-glottic view could not be obtained. There were otherwise only the usual appearances of a chronic hypertrophic laryngitis. The disease gradually spread and finally appeared on the other side. The usual symptoms of aphonia and dyspnœa slowly appeared and grew so severe that a tracheotomy was finally done under cocaine. Much relief followed, but an attack of influenza caused considerable discomfort. The cannula in the neck was constantly clogged up by a thick, tenacious mucus, later becoming bloody. The patient finally died from exhaustion after a suffocative attack. The autopsy showed the disease confined to the ventricular bands and larynx. The cords were thickened, but the neoplastic formation did not extend below the tracheal wound. Intrinsic cancers grew slower than extrinsic. They were less active and malignant, and consequently less liable to recur after removal. Pyoktanin had been used locally and given internally in doses of three grains. It upset the stomach and did not seem to have any effect on the local process. The cause of the dyspnœa was probably the projection of the mass into the windpipe.

The Laryngo-Tracheal Neoplasms of Tuberculosis.—Some remarks were made on this topic by Dr. John N. Mackenzie, of Baltimore. He divided these growths into the following classes: First, papillary hyperplasia. These were granulation like bodies springing up from the edges and base of ulcers. They varied in size and shape. They rarely came from simple ulcers or from the later aphthous ulcerative condition of later tubercular states. The ulcer was separated from the healthy tissue by a zone of hyperplastic connective tissue, forming a sort of projecting barrier to isolate the morbid process. The granulations were made up of connective-tissue fibres and cells with enlarged and tortuous capillary vessels. The process was conservative and an effort of nature to heal by granulation, though she generally failed in the attempt. They should therefore not be removed unless so numerous as to occlude the lumen of the air-tube. Second, little tumors, warty, acuminate or leaf-like, which in structure did not differ from laryngeal papillomata. They generally occurred after a chronic catarrhal state, but sometimes in the anæmic stage, and heralded, so to speak, the approach of the more severe process. They were generally found in the inter arytenoid space. Stoerck regarded them as an infallible sign of the tubercular process. They were best treated by chemical cauterization, unless they were large enough to snare. They were not, as far as we knew, connected with true maxillary tubercle. Third, and most important, solitary tubercular tumors, isolated and made up of a mass of miliary tubercles set in a vascular net-work of connective tissue. They grew mostly from the submucous connective tissue and were less apparent at the surface. The treatment is problematical, as we do not know how deep they go.

Dr. J. Solis-Cohen narrated the history of a patient in whom a tuberculous process had invaded one lateral half of the larynx as well as the epiglottis. The cords were not affected. Considerable of the growth was removed by sharp scissors while the remaining parts were treated by lactic acid applications. Creasote in large doses was given and the patient recovered. There was no ulceration in the mass. One pulmonary apex was softened.

Dr. Sajous regarded the inter-arytenoid space as the favorite seat of such deposits. Chromic acid had given, in his hands, the best results.

Dr. Mackenzie would class Dr. Cohen's case in the second group, but as no bacilli were found (a fact stated by Dr. Roe, who also saw the case), he should be inclined to doubt the accuracy of diagnosis. He did not believe that the tumor would have reached such a size without ulceration if it were tubercular. Three different microscopists had examined Dr. Cohen's case, and no two agreed as to the nature of the growth.

The Relations of Disturbances of the Mucous Membrane of the Upper Air-Passages to Constitutional Conditions.—A discussion on this topic was opened by Dr. Beverley Robinson, of New York. Attention was called to the fact that the modern tendency of medical thought was to throw doubt on the belief in the existence of the so-called diathesis. Disease was looked upon as originating from some local cause, seen or unseen. Hence more local treatment was necessary. The tendency of modern specialism was to produce a limited mental horizon. Mucous membranes seem to be the habitat for disease-germs, yet constitutional symptoms may precede the localization of the morbid process. Such bodily tendencies as rheumatism, scrofula, syphilis, gout, alcoholism, lithæmia, etc., all tend to make the local condition worse. Attention was called to the points of differential diagnosis in some of the common throat affections.

Dr. Robinson believed that a malarial tendency underlay many of our ordinary catarrhal colds. In cases of the latter, the hematozoöid had been found in the blood, and these cases had yielded promptly to quinine, while local treatment was of very little service. Quinine would sometimes cease to relieve, then phosphorus and strychnine were indicated.

A paper on the same topic, by Dr. T. A. De Blois, of Boston, was also read by Dr. Robinson.

Dr. Mackenzie did not regard scrofula as a distinct entity. According to the pathology of the present day, scrofula is tuberculosis.

Dr. Jarvis could not accept this exclusive view. Some scrofulous manifestations looked like tuberculosis, while others resembled hereditary syphilis.

Dr. Mulhall would define scrofula as "the product of a conception at the time of which one or both of the parents were not in a condition to procure healthy offspring." This unfavorable condition might be due to alcohol, senility, starvation, etc., as well as other causes.

Dr. S. Solis-Cohen believed in the existence of a true scrofula. It was the child of syphilis and the parent of tuberculosis. To understand the subject we should study syphilis and tuberculosis in their relation to the production of cell energy. There was not enough constructive force in a scrofulous child to overcome the destructive energy and the opposition to cell growth. The French had used for this condition the terms "hypertrophy" and "congenital dystrophy."

Dr. Glasgow considered that the tubercle bacilli had no reference to scrofula.

Drs. Bosworth and Ingalls also discussed the paper.

During the sessions of the Association the following papers were read by title: "Observations on Paralysis of the External Tensors of the Vocal Cords," by Dr. George W. Major, Montreal; "Some of the Uses of Pyoktanin in Diseases of the Upper Air-Passages," by Dr. R. P. Lincoln, New York; "The Surgical Treatment of Tubercular Laryngitis," by Dr. D. Bryson Delavan, New York.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. S. W. Langmaid, of Boston; *First Vice President*, Dr. M. J. Asch, of New York; *Second Vice-President*, Dr. S. Johnston, of Baltimore; *Secretary and Treasurer*, Dr. Charles H. Knight, of New York; *Librarian*, Dr. T. R. French, of Brooklyn; *Council*, Drs. W. C. Glasgow, of St. Louis; F. I. Knight, of Boston; D. Bryson Delavan, of New York; Harrison Allen, of Philadelphia.

Dr. J. H. Bryan, of Washington, was elected a Fellow of the Society.

The next session will be held at Boston in June, 1892.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held in the Grand Army Building, Washington, D. C., September 22, 23, 24, and 25, 1891.

(Continued from p. 381.)

Third Day, Thursday, September 24th.

Epidemiology of Influenza and Its Relations to Catarrhal Fever, was the title of a joint paper by Drs. R. G. Curtin and E. W. Watson, of Philadelphia, read by the former. Catarrhal fever, due to the same specific cause, precedes and is associated with epidemic influenza, which latter represented a most violent outbreak of the more causative influences. Catarrhal fever appeared a year in advance of the influenza epidemic of 1889. This catarrhal fever presented a symptom group heretofore undescribed in the literature of medicine. It represents the same morbid process as that productive of influenza. Taking the experience of Australia as a criterion, he thought we had every reason to expect continued manifestations of influenza during the next two years. In Australia the disease had recurred during five successive years, 1885, 1886, 1887, 1888, and 1889, the symptoms being identical with those observed in our own country during corresponding periods of time. He thought that the type of influenza which would next appear would closely simulate in symptomatology the local appearance of diphtheritic processes, and would also assume the type of an epidemic cerebro-spinal or spotted fever. He had no doubt as to the positive contagiousness of the disease.

Reports on the Late Epidemic of Grippe.—Dr. A. Alexander Smith, of New York, reported observations upon some of the less common phenomena of influenza, especially as they involved the skin, nervous, mental, and digestive systems. He had noticed several instances of cutaneous symptoms resembling the lesions of scarlet fever and of measles. An urticaria frequently occurred in cases with marked gastric disturbances. Purpura had also been observed in several instances. Acute mania, not associated with high temperature or with alcoholic habits, had also been noted. The delirium in certain cases resembled that of mania-a-potu in subjects non-alcoholic. In old cases of chronic alcoholism the disease acted as an injury does in such cases, producing a condition like delirium tremens. Suicidal tendencies he had frequently observed; homicidal tendencies had been rare; convulsions, and the many paralyses mentioned by other writers, he had not observed. In certain cases characterized by quite marked gastric intestinal disturbance, he had noted marked jaundice as a complication or sequel. He cited statistics collected from the tables of the Board of Health in New York, bearing upon the mortality from pneumonia, bronchitis, and pulmonary phthisis, during the five years preceding the outbreak of influenza, as compared with the deaths from these diseases occurring during the two years of epidemic grippe. These tables showed a large increase in the percentage from pneumonia and bronchitis, but none from pulmonary tuberculosis. According to Dr. Tracy, at least eight hundred thousand New Yorkers had been affected by the epidemic with a personal attack in 1891, while Dr. Edson placed the number at nine hundred thousand or more. As illustrating the effect of occupation and atmospheric exposure to the development of the disease, these statistics showed that of the police and letter carriers of New York ninety per cent. had contracted the disease, the remaining ten per cent. constituting the proportion engaged in indoor or clerical duty.

Dr. Curtin, of Philadelphia, read a report prepared by Dr. Watson in conjunction with the reader's description of the disease, as it was observed in Philadelphia, based upon five thousand cases. They had recognized a circulatory, nervous, alimentary, catarrhal, and rheumatic type of the disease, and found that depression of the circulation and nervous system had been the two conditions requiring most vigorous consideration in treatment. Cases of grippe ending fatally did so usually through the involvement of respiratory function, and, secondly, through the medium of heart failure.

Dr. Nunn, of Savannah, described the disease as it appeared in the South. The earlier cases, during the first outbreak, were simple in character, and presented no special difficulty in their management. Later the disease assumed a different type, and appeared to be distinctly a neurosis. All symptoms could be explained, no matter how varied, upon this hypothesis. He had found stimulants most effective in the treatment. Among these ammonia salts and nux vomica had been most beneficial. Opium he had found attended with very unfavorable results in all cases. He recalled one death undoubtedly due to this cause. Hydrastis had also proven a valuable remedy in the disease. Convalescence had been invariably tedious, and he could recall cases not yet recovered from the effects of attacks incurred two years ago. Among the more remote effects he had noticed a tendency to light up diathetic tendencies—the arthritic would develop rheumatic attacks, etc. A change of climate had always proven beneficial in hastening convalescence.

Dr. Mulhall, of St. Louis, had confined his observa-

tions to the effects upon the respiratory organs. The winters during both epidemics had been unusually mild, the rainfall and high winds had been excessive, the snowfall slight, and mean average temperature high. Not many deaths had occurred from uncomplicated attacks at the time, but many leaths within a year succeeding had occurred from pulmonary consumption. The vast majority of cases were not tuberculous when attacked, as proven by microscopical examination. A peculiarity proven by clinical and post-mortem observations was, that the materies morbi of la grippe often aroused dormant or latent pathological processes, which became then rapidly fatal. Another peculiarity noted was the long-continued congestions preceding active inflammations, not uncommonly relieved by hemorrhage. The recognition of this peculiarity is an important matter in the lungs, in order to prevent the often noted cycle of congestion, hemorrhage, pneumococci, tubercle bacilli, and death. This latter clinical picture was proven in patients under his care, by the bacteriological demonstrations of Dr. Ludwig Bremer. As a rule, the disease did not tend to suppuration. A noteworthy result of influenza had been observed by the speaker, in a loss, more or less permanent, lasting in some instances more than a year, of the singing voice in professional vocalists, especially the upper register. He did not believe it possible to determine the question of contagiousness, although it was presumably true. One attack gives no protection. He had observed a recurrence of the disease in one patient five times in two years. The clinical picture and the remarkable sequelæ prove that the nervous system plays the most important rôle, anatomically speaking. Vaso-motor paresis, peripheral and cerebral, is the dominant pathological feature.

Dr. Ingalls, of Chicago, had observed radical differences in symptoms, referable to the nervous, respiratory, and digestive systems, in the last epidemic, as compared with the year previous in the disease, as it appeared in Illinois. The nervous symptoms were much more pronounced, as manifested in neuralgic affections, prostration, and mental involvement. Derangements of the digestion were more pronounced. The epidemic of last year had been followed by a large number of cases of fever closely simulating typhoid fever, but lacking some essential features of the latter disease. These fevers were from ten days to two or three weeks in duration. The respiratory symptoms differed in the type of pneumonia observed. In the first epidemic the catarrhal form prevailed, while last year the croupous type was the more frequent The nasal and throat symptoms were noticeably mild. Pleural affections were more common, and he had observed a tendency to suppuration in the pleural cavity as not uncommon. Tracheitis among the respiratory symptoms was the most common of all, giving rise to a violent cough of spasmodic character easily re-excited weeks or months after recovery by undue exposure. He had seen offensive muco-purulent discharge with this cough. In the treatment he had found the bromides effective for cough, other treatment had been symptomatic.

Dr. Munro, of Boston, also read a report on the subject, based upon peculiarities observed in the disease as it prevailed in the New England States.

In the discussion which followed, Dr. Levick, of Philadelphia, referred to a paper, published by him in 1864, upon the subject of epidemic influenza, which illustrated the remarkable consistency in the symptomatology of the disease regardless of changes in methods of living environment or alterations in race peculiarities. He had described in the paper mentioned a busy delirium like that of mania-a-potu, similar to that referred to in the discussion to day. Scarlatina-like eruptions, cutaneous lesions resembling measles, urticaria, lichen tropicus, and erysipelatous patches had all been mentioned as appearing among the manifestations of the disease as it occurred in 1864. Jaundice he had also noticed and described. He believed the relationship of epidemic cerebro-spinal meningitis, or spotted fever, to epidemic influenza to be a close one etiologically. In 1864 the two diseases occurred simultaneously as an epidemic. He suggested an identity of the two with only a difference in degree. Gallup, Trent, North, and Job Wilson, writing in the earlier part of the present century, had all advocated the doctrine of identity. If we should have a cold winter this year, he felt confident we might expect an epidemic of cerebro-spinal meningitis.

Dr. Ward said that the disease manifested its most conspicuous action upon the central nervous system, and that such action was of the nature of a functional derangement, not an organic change. One attack did not give immunity from others, as he had known the same patient to suffer several times. Influenza only lit up old pathological processes by reducing the patient's vitality and consequent resistance to disease.

Dr. Ford, of New York, doubted the contagiousness of influenza.

Dr. Musser, of Philadelphia, cited the published experience of Dr. Trudeau, of the Adirondack sanitarium, in support of his belief that the disease was communicable by personal contact.

Dr. Ruedi, of Denver, related the cases of four mountaineers, completely isolated in the Alps of Switzerland, who did not suffer from the disease for months until after one of them had undergone exposure by a short visit to a village in the valley below where the disease was prevalent, he developing the grip three days later and all his companions, hitherto free, falling victims.

Dr. A. H. Smith, of New York, spoke of the treatment which had been most effectual in his cases. He had used with great benefit in his practice a combination of phenacetin, $3\frac{1}{2}$ grains, camphor, $\frac{1}{2}$ grain, and atropia, $\frac{1}{200}$ grain, which relieved the pain quickly and controlled temperature without any cardiac depression or excessive sweat. He had used quinia as a tonic in convalescence and had not had a fatal case or any case of pneumonia as a complication in his private practice, though many cases had undergone a tedious convalescence. Codeine had been of great service in the obstinate irritating cough sometimes observed. He was not able to form any positive opinion as to the contagiousness of the disease.

Dr. Von Ruck, of Asheville, N. C., rather advocated a belief in the personal communication of the disease. In the sanitarium at Asheville, with some forty odd guests, no cases occurred during the first six weeks of the epidemic prevailing in the city. The first cases occurred in servants of the institution having outside communications. Only three cases occurred among the inmates of the sanitarium.

Dr. Fiske, of Colorado, had noted nervous symptoms as peculiarly prominent in cases which occurred in Colorado. He had observed that the attacks during the outbreaks this year and last were markedly different. This year none of the cases had shown any intestinal symptoms. In Colorado invalid consumptives had shown a marked exemption from the disease, and when they did develop influenza it was invariably of a mild type, and he had no recollection of a single death in a phthisical patient. New patients coming from the East, however, during the past year had almost invariably dated their disease to an outbreak of la grippe.

Dr. Johnston, of Washington, did not think it possible to explain the widespread simultaneous development of la grippe as being due to personal contagiousness. Epistaxis, which had been referred to in one of the reports as rather a conservative symptom, he had found invariably to be a dangerous complication. Intestinal hemorrhage he had also observed and the patient narrowly escaped death. He had seen several cases in quite young children, contrary to the belief that young children were exempt.

Dr. Van Bibber, of Baltimore, had met with an experience which tended to establish his belief that the dis-

ease was contagious. He had found narcein, in doses of one-quarter grain, very valuable in relieving cough and neuralgic pains.

Dr. Smith, of St. Augustine, stated that in Florida the disease did not appear at all during the first year of its prevalence in America. Last year the cases were mild, free from complications, and with no abdominal symptoms. The mortality was very slight.

Dr. Gilrou, of the United States Army, described a personal attack in which mental despondency was the most marked characteristic. Dr. Levick's description of the disease as it occurred in 1864 was equally appropriate and accurate in its bearings upon his own case.

Fourth Day, Friday, September 25th.

Diphtheria at High Altitudes.—In a paper upon this subject, Dr. W. A. Jayne, of Georgetown, Col., from observations based upon 68 cases observed personally, reached the conclusion that a high altitude exerted a decided restraining influence upon the bacteria of diphtheria; that few cases developed through contagion, and that bad sanitary surroundings were in a direct ratio to the virulence of the disease. Of the 68 cases recorded the mortality was twenty-five per cent. Twelve died from sepsis, 5 of which were hopeless when first seen. Of the total number of cases, in 32 the formation of membrane was limited to the pharynx, and of these, only one died. In 31 cases the nasal mucous membrane was attacked, and 14 of these cases proved fatal; of 4 laryngeal cases, 2 died. Nasal involvement, as in lower regions and the East, proved most fatal. In the cases which recovered, convalescence was prompt, and the disease was free, comparatively, from complications. Palatine paralysis was not uncommon, but disappeared quickly without treatment.

Dr. Von Ruck, in the discussion, asked if the method of chlorine injection under the membranes, recommended by Seibert, had been tried in the reported cases, and if so, with what result.

Dr. Tyndale described the method of Siebert in using chlorine water, referring to the fact that it was only of value in tonsillar deposits.

Dr. Rogers, of Colorado, had noticed that the majority of cases occurring in Denver had been characterized by nasal involvement. Heavy, wet, spring snowstorms, which were not common in Denver, left much moisture, and were always followed by outbreaks of diphtheria. The disease is next to typhoid fever, in its frequency and malignity, in the high altitudes of Colorado. By the free use of mercury, however, he had overcome his dread of the disease. His treatment consisted of the bichloride of mercury, in doses of from $\frac{1}{4^{\frac{1}{8}}}$ to $\frac{1}{12}$ of a grain, every two hours, for twenty-four hours, the only limit to the dose being the effect upon the membrane. He did not fear the drug, and by its use in conjunction with hydrogen peroxide locally, he had reduced his death-rate seventy-five per cent. Deaths from nephritis were far less common under mercury than when he had used iron alone.

Dr. Glasgow also participated in the discussion.

The Pretubercular Condition.—Dr. J. Hilgard Tyndale, of New York, expressed the belief, in a paper with this title, that the development of tubercular disease in the individual is largely determined by the presence of an inherent destructive metabolism, as opposed to a constructive metabolism in others, the terms being synonymous with those of scrofulous and fibrous diathesis, according to the nomenclature of Loomis. An investigation of the pretubercular condition involves the acceptance of two maxims or propositions: First, that all more than temporary departures from a condition of well being of which the patient has been conscious for weeks or months, and which cannot be made to fit into the frame of recognized acute or chronic, functional or organic, disease, represent the pretubercular condition. Three stations are to be noted: 1st, That made up of the general malaise just mentioned, which is entirely subjective; 2d, changes in the respiratory elements of rhythm, pitch, and finally, of quality; 3d, dry, followed by moist râles. The first station is the true pretubercular condition; the second and third merge into regular tubercular invasion. Second maxim: The pretubercular condition is a tubercular colonization in the lungs, as yet undemonstrable by physical signs, engrafted upon those whose general condition has made them fit subjects for invasion.

Dr. Von Ruck, in commenting upon the writer's views, emphasized the radical importance of an early recognition of the so-called pretubercular condition as representing the first stage of tubercular invasion where auscultation and percussion as yet furnished no clue. a condition soon merging into readily demonstrable changes in the respiration, and finally, râles. Instead of sending cases with large cavities, in a hopeless state, to suitable climatic resorts, this much-neglected first stage should claim the attention of physicians as offering a field for positive curative results.

The Waters of Richfield Springs.—Dr. C. C. Ransom read a paper descriptive of the methods in use at the Springs in the administration of the waters and baths. The chemical character of the waters and the indications and contra-indications in disease were elaborated with a view to the selection of appropriate cases by physicians sending patients for treatment. Nearly all forms of skin disease and the various types of rheumatism were benefited or cured by the waters.

The Climatic Treatment of Chronic Diarrhœa was considered in a paper read before the Association by Dr. W. W. Johnston, of Washington, D.C. The observations and conclusions embodied in his paper were applicable not only to forms of chronic intestinal catarrh with diarrhœa, but to those also in which the discharges consist of mucus passed alone or in connection with more or less solid fecal matter. These cases are often most obstinate, and resist all efforts at home treatment. Two clinical varieties were considered: First, the primary and simple form of chronic intestinal catarrh, with or without follicular ulceration, the type of which is the chronic diarrhœa of armies and prisons, observed also in civil life; second, a form most frequently met with in practice, more complex in its origin and nature; it is not primary, but is the outcome of prolonged ill-health characterized by chronic indigestion and various nervous phenomena. The causes are overstrain of the nervous system brought about in men by professional or business cares and anxieties, and in women by frequent childbearing and a mother's many worries. The patient passes successively through the stages of gastro-intestinal indigestion, hepatic disorders, and constipation; there may be lithæmic, neurasthenic, or gouty symptoms, the stools sooner or later contain mucus, pure or floating in a watery fluid.

This complex disease can sometimes be cured by partial rest from work, by dietetic regulations and medicine. Often, however, only temporary relief, or failure, attend every effort, and radical measures, involving changes of residence and climate, become necessary and must be adopted. Travel is not to be recommended, as the inconveniences, discomforts, and fatigue either delay recovery or aggravate the disease. Ocean voyages are of no benefit except in mild cases. A prolonged residence in a suitable climate is the best procedure, and the locality selected should have the following conditions: 1st, Surroundings which give relief to mental care and supply pleasurable diversion; 2d, an atmosphere which can give the greatest activity to the digestive processes; 3d, meteorological conditions which will not lead to chilling of the surface or "taking cold;" 4th, a warm, equable climate, which is generally a humid one, is not as beneficial as a cool and dry climate both in winter and summer; a dry, porous soil, a clear sky, with but little rain fall, add to these advantages. In summer, for severe cases, the Catskills, Adirondacks, or White Mountains; in winter,

Western North Carolina, Northern Georgia, and other sections of the Appalachian chain fulfil the indications. Aiken and other similarly situated places were now better for those who cannot stand the cold of greater altitudes. He knew no reason why the high regions of the Rocky Mountain area might not answer as well, but based his paper only upon observations from personal experience and with Eastern climatic resorts. No published data as to the effect of this Western region, including Southern California, were accessible for reference or deduction. The paper was announced as only preliminary to a further and more extended consideration of a most important subject.

The Influence of High Altitudes upon Hereditary Tuberculosis, and its Effects upon some Forms other than Pulmonary.—Dr. H. B. Moore, of Colorado Springs, contributed a paper upon this subject. The presence of a large number of married phthisical invalids in many of the cities and towns of Colorado, notably Colorado Springs, had rendered pertinent the question as to the influence of these high altitudes upon the inherited predisposition of different forms of tuberculosis. Furthermore, the marked relative immunity from phthisis which exists at high altitudes, together with the radical improvement experienced by sufferers from phthisis who go there, has suggested the possibility that not only the pulmonary form of tubercular disease, but other forms, as bone and joint tuberculosis, may present examples of an analogous immunity and benefit.

With a view to determining these two points, letters of inquiry were addressed to practising physicians of Colorado. From the answers received, and from personal investigation, the conclusion is justifiable that tuberculosis in any form seldom originates in Colorado, even among those strongly predisposed by heredity. In other words, the climate of high altitudes is an efficient antidote to the tubercular diathesis. In Colorado Springs, for example, with a population of twelve thousand, composed almost entirely of phthisical invalids, notwithstanding the strong hereditary taint necessarily existing, there have been but seven instances of phthisis originating there during its entire history. With regard to cases other than pulmonary the preponderance of opinion was quite decidedly to the effect that their infrequency and the favorable results obtained were quite equal to what obtains in pulmonary phthisis, the inference being that the therapeutic influence is not so much a matter of chest expansion, and improvement in local nutrition consequent upon it, as it is a general tonic influence maintaining a high degree of nutritive integrity throughout the entire system.

The Climate of Southern Arizona.—Dr. Thomas Darlington, of Bisbee, Ariz., read a paper with the above title.

A Contribution to the History of Leprosy on the Eastern Coast of the United States.—Dr. W. H. Geddings, of Aiken, S. C., presented a communication concerning the simultaneous occurrence of three cases of lepra in one family. A list of all the cases of the disease that had occurred in Charleston, from 1847 to 1882, constituted seventeen in number. A few years later another case was seen by the writer. She was not a resident of the city, but of a neighboring village on the coast. Including the three described in the present paper, twenty-one well-authenticated cases have occurred within the last thirty-four years in and near Charleston. These cases throw but little light on the etiology of the disease. They were nearly all young adults or persons of middle age. They embrace every grade of society from the descendents of the old Huguenot families, who immigrated to this country hundreds of years ago, down to the humblest domestic servant. Four were Jews, and the others Christians; sixteen were whites, four mulattoes, and one a full-blooded negro. They were all natives, and with the exception of one, whose parents were Irish, their ancestors had lived in the country for a number of years. As the negroes predominate in this section the fact that only five out of twenty-one were colored would indicate that here this race is less liable to the disease than the whites. In one instance a mother and her daughter were affected with the disease, and in another a father and his son.

In South Carolina the disease appears to be confined almost exclusively to the sea-coast. It will be remembered that this is also the case in Norway. These unfortunates are in no way restrained, and when not too ill, may often be seen walking about the streets of the city. Their appearance excites commiseration, but no one fears to come in contact with them. They live with their families, but mingle freely with the outside world. The number of lepers in the city at any one time has varied from one to three, and as the disease has never evinced the slightest disposition to spread there has never been any fear of its becoming epidemic. How long this will remain the case is doubtful, as Dr. James C. White says that it is spreading rapidly in Louisiana and Florida.

Family History of the Three Cases.—Of the paternal grandparents nothing is known. The father was a Sicilian sailor. He made several voyages between Sicily and New York, but there is no reason to suppose that he ever visited countries in which leprosy is endemic He soon abandoned the sea and removed to Charleston, where he was engaged in business for a number of years, and eventually died there of congestion of the brain. The mother is a strong healthy woman, of native parentage, fifty-eight years of age, who has borne twenty children, eight of which are still living. On neither side is there any evidence that the ancestors suffered with lepra.

General History of the Development and Course of the Disease.—In the autumn of 1885 Charleston was visited with a severe cyclone, which inundated portions of the city with salt water from the adjacent rivers. The family inhabited a house in the inundated district, and had stored in the cellar some of their carpets and other household furniture. Two days after the flood, when the water had partially subsided, two of the sons, and one of the daughters, all of them apparently in perfect health, undertook to remove the damaged effects, and to accomplish this work were compelled to wade through water which reached to their hips. The water is said to have presented a dirty greenish appearance. They were engaged in this work for two days. On the evening of the second day, while drying themselves before the open fire, they all noticed a number of bullæ on the outer side of the left leg. These bullæ, at first about half an inch in diameter, gradually enlarged, and finally coalesced into large blebs extending from the external malleolus half-way up the leg. They were filled with a clear, serous fluid of a bright yellow color. In the course of two or three weeks these gradually dried up and desquamated, leaving purple spots, which later on assumed the appearance of white cicatrices. As the bullæ disappeared it was noticed that the affected area was devoid of sensation. The skin then assumed a brownish-yellow color, almost bronzed. Tubercles were developed over various portions of the body, but were larger and more sharply defined on the face and ears than elsewhere. Between the tubercles the skin was much thickened, in some situations hanging in folds, especially where it is loosely attached, as, for instance, below the lower lids. The natural wrinkles over the face were exaggerated into deep furrows. The tubercles over the eyebrows, nose, and ears were more prominent and larger than elsewhere, and with the thickening and wrinkling of the integument gave to the face the lion-like expression so characteristic of leprosy.

The following are, in brief, the clinical histories of the three cases :

Case I.—F. A——, is now twenty-four years of age. In the autumn of 1885, while apparently in perfect health, he assisted his brother and sister in removing their damaged effects from the flooded cellar. On the evening of the second day, while drying himself before the fire, he

observed a number of blisters on the lower and outer half of the left leg. The subsequent course of the disease corresponded in almost every respect with the general description just given. In this case the disease continued to advance for two years, during which the patient was quite ill and suffered considerably with pain in the parts affected. About the beginning of 1890 the general cutaneous hypertrophy began to diminish and sensation reappeared in many situations which hitherto had been anæsthetic. The general health of this patient is at present excellent, and he is quite sanguine of his ultimate recovery.

Case II.—R. A—— , seventeen years of age, a younger brother of F. A——, was affected at the same time and in the same manner as the elder brother. Bullæ filled with serous fluid appeared on the external half of the left leg, chiefly over the ankle and knee, which after drying became white maculæ. These spots were devoid of sensation. The disease soon appeared on the face, then on the trunk, and finally on the upper extremities, pursuing the same course as in Case I., except that the general health was more seriously impaired.

Case III.—A. A——, twenty years of age, a sister of the two young men, worked with them in the stagnant salt water, and like them had an eruption of bullæ on the outer surface of the left leg. These gradually dried up, leaving in their places white patches which were so devoid of sensation that a needle could be passed through the skin without causing the slightest pain.

Status Præsens.—The patient is slender and somewhat emaciated. The chest is flat and contracted, and for some time past the patient has had cough with evening fever. Her general appearance is that of a person well advanced in phthisis.

This is the only instance on record in this country, the speaker said, in which leprosy has attacked three members of a family at the same moment. All three had worked in stagnant salt water for two days and were simultaneously attacked while drying themselves before an open fire, and in each case it was the left leg that first presented evidences of the disease, and invariably on its external aspect. Whatsoever the remote cause of the disease may have been, no one will doubt that in these cases the exciting cause was heat acting upon skin, which had been previously softened, and perhaps irritated, by continuous immersion in salt water.

ASSOCIATION OF AMERICAN PHYSICIANS.

Sixth Annual Meeting, held in the Grand Army Building, Washington, D.C., September 22, 23, 24, and 25, 1891.

(Continued from p. 382.)

Third Day, Thursday, September 24th.

The Relations Between Arterial Disease and Visceral Changes.—Dr. George L. Peabody, of New York, opened a discussion on this subject. The causes of arterio-sclerosis are varied, and it is hard to find the right one in every case. Whether due to syphilis or not, we cannot always say. There are different facts which assist us to look for the cause. We look for the lesion in the blood-vessels, and in particular in the arteries. From an examination of the intima of the artery it cannot be said what is the cause, just as in phthisis we find well-marked sclerosis, not tubercular in nature. Dr. George Johnson and Drs. Gull and Sutton have done the best work on the subject. They described a thickening of the walls of the arteries in Bright's disease, and said they were due to arterio-sclerosis. He thought it was in part due to the faulty methods of preparation, and particularly to the glycerine in which they had been preserved. This was much like a hyaline degeneration. During the past fifteen years much attention has been paid to this condition. Thomas has made some valuable contributions to this work, and his conclusions are very important. The cause of the fibrous growth has hitherto escaped detection. It is hard to find out which the cause and which the effect of the change in the kidneys and in the blood-vessels. After partial study he came to conclusions which we may in part accept. The interstitial inflammation in the kidney is the cause, not the effect, of the change in the arteries. The changes in the artery begin after birth. This change extends gradually. What causes this regular distribution of these lesions, and why are only the organs in question affected while the rest of the system escapes? First, there is a slowing of the blood current in the aorta; the circulation in the two umbilical arteries ceases at birth; the arteries become disproportionately large. The result is that the blood-current passes through it more slowly. This cannot be demonstrated but must only be deduced. The new-growth in the intima tends to reduce the size of the artery, and this is due to the cessation of the circulation in the placenta. The same changes occur in arteries whose size is suddenly diminished by surgical procedure, ligature, etc. There is a lesion in the intima, the endothelium of the blood-vessel becomes affected, a dilatation takes place, a slowing of the blood current, changes in the vasa vasorum, a thickening; the sensitive nerve-filaments in the arterial walls appreciate the change in the vasa vasorum. The tension of the arterial walls is the cause of the form taken by the growth under different circumstances. As soon as the blood-current is settled the changes stop. The change is a purely mechanical one. The best explanation of it is *a priori* and theoretical. Diseased arteries give less blood to the organs than they require to have, and this goes on causing more and more change. One authority says that the alteration of the blood pressure in the vessels causes the trouble; if it is diminished the endothelium in the vessel grows. How can we explain this? The cause is hard to explain. It is a general disturbance of nutrition. We may have senile changes, changes in the arteries, veins, or capillaries, and these may occur in a great variety of conditions. It is seen with corresponding changes in the kidney, testicles, and other parts. Heredity, gout, rheumatism, functional arterial strain, according to Thomas, and many other causes may be at hand.

The effects of these changes in the arteries may lead to an aneurism. The connection from an etiological point of view is not fixed. It is not proved that arterio-sclerosis is the sole cause of this disease. The walls, being weakened, dilate, they are less elastic than normal. There is increased pressure and the lumen of the vessel is increased too. At first the intima of the artery is able to withstand the pressure, but later it cannot. This dilatation can be produced artificially in other vessels, but it cannot be done in healthy arteries. The time within which an aneurism can be produced while this change is going on is supposed to be one year, and after that time the intima becomes so reinforced that the aneurism cannot be formed. This is the rule for each vessel, so that as changes occur, first in one vessel and then in another, the danger of the formation of an aneurism in any one vessel would exist during one year after the vessel was affected; but as all the changes do not go on in all the vessels at the same time, the period of danger would be between thirty-five and forty-five years. We want stronger evidence of the truth of the statement than is given here. The diagnosis of this trouble can also be made from an ophthalmoscopic examination. The vessels are seen to be tortuous, pulsating, and there is an opacity in their walls, with diminished lumen. There may be anæmia of the central external artery, with varicose veins, and at times complete obliteration, while the rest of the arterial system is intact. The carotid vessels are generally early affected. It is a common cause of the left ventricular hypertrophy, which is caused by the overtaxation of the muscular fibres of the heart, with a diminution of the elasticity of the arterial walls. This is often of syphilitic origin, and in this case forms a com-

mon symptom. There is at times great disturbance of the brain function, and death has occurred without brain lesion being evident. The brain symptoms may be with or without thrombosis. If it is from syphilis it is amenable to treatment, but if not treated it is apt to go on to cerebral softening. He then related a case, in which some of the lesions were dependent upon arterial sclerosis, in which there was rupture of the diseased arteries. It may cause sudden blindness.

Dr. W. T. Councilman, of Baltimore, continued the discussion. Diffuse anterio sclerosis is a very interesting study. The paper of Gull and Sutton was the first great work in this direction. It commonly begins in the kidneys, but at times it is apparent in other organs when the kidneys are free from it. He quoted Thomson's theory of it. He, in connection with Dr. William T. Howard, Jr., had examined 41 cases at the Johns Hopkins Hospital and had made three classes. 1st. The nodular form, which was of little interest. There are changes in the arteries and larger vessels, and there were large plaques in the intima of the vessels and their media was thin. 2d. The senile form, in which the vessels were calcareous and in them were fissures, loss of substance, etc. They were dilated, elongated, tortuous, broad, thinner than normal. 3d. Where there was also a change in the liver and kidneys. In the latter organs the cortex and medullary portion were both affected, but the cortex the most. The microscope showed process of atrophy and degeneration. Of 27 cases, the youngest was twenty-three and the oldest sixty; the rest were between forty and fifty-five. Of these 27, 14 were white and 13 colored. Most of them were of large build and muscular, and the most marked changes were found in the aorta or large arteries. There was some dilatation, but it was not homogeneous. The changes in the kidneys were not constant, the liver was increased in size, the lungs were little affected, and the pulmonary artery was free from disease. The most marked renal changes are degeneration and atrophy of the connective tissue. There were also changes in the media of the large and small vessels.

Dr. William T. Ord, of London, did not believe that the changes described by Gull and Sutton were caused by glycerine and other substances used in the preservation of their specimens, as Dr. Peabody suggested. He thought it was a general disease affecting the whole system, a disease similar to gout, and not a disease affecting one organ or one set of organs only. He referred to a very typical case which he had seen with Sir W. Gull, in which the cause was evidently due to eating and drinking. In England a large number of people eat often and heartily at night, and accompany their eating with frequent libations of strong wines. This, combined with a life of indolence or little exercise, tends to develop gout, arterial disease, etc. He believed it was very important to examine the great-toe joints in these cases. He examined the great-toe joints in 30 cases, and in 17 he found deposits, and of these 17, 12 had granular kidney; of the remaining 5, 3 had some change in the kidney.

Dr. W. T. Gairdner, of Glasgow, noticed that Dr. Peabody did not refer to dissecting aneurisms. He referred to a case of his own of sudden death in which there was kidney trouble, the death being due to a dissecting aneurism after a sudden strain. He was struck with the fact that Dr. Peabody gave the years of usual attack, with the assertion that this disease did not attack after a certain year. He also did not believe there was a difference in the two radial pulses, as Dr. Peabody had stated. He agreed with Dr. Ord in the connection between gout and this disease, and the peculiarity of London in this respect. In London there was a large leisure class that drank and ate much and took little exercise. Glasgow was not so prone to gout; was more so since the disappearance of Glasgow punch, for since the people had ceased to drink this comparatively harmless beverage they had taken to stronger and more dangerous drinks, with an increase of gout and arterial disease.

Dr. William T. Councilman, of Baltimore, did not mean to belittle the work of Gull and Sutton; he said they were pioneers in this direction, it was the first and best work, although they did make some mistakes and we have learned something more of the disease since their time, especially by our improved knowledge of histological methods. He thought the idea of examining the great-toe joint, as suggested by Dr. Ord, was an excellent one, and he should adopt it in the future.

Intestinal Perforation in Typhoid Fever.—Dr. Reginald H. Fitz, of Boston, Mass., read a paper with this title. He thought there were many contrary views concerning the prognosis of intestinal perforation in typhoid fever. Some observers claim that no case of recovery from intestinal perforation after typhoid fever ever occurs. There are now more and more reports of recovery from this complication of typhoid fever being offered. The symptoms of perforation may be present in the absence of this lesion, and the lesion may be present without characteristic symptoms. There are evidences of recovery from typhoid fever showing symptoms of perforation. The expulsion of pus, food, etc., from the vaginal walls is a sign of perforation, and if patients recover from this, why may they not recover from perforation? If possible, find the seat of perforation, and cut down on it and drain. To be successful this operation should be done early. Recovery has taken place in several cases by spontaneous discharge of the matter or by resolution.

Dr. J. M. Da Costa, of Philadelphia, said that when we think there is a perforation we should try to find out where it is. He related two cases of unsuccessful operation for perforation. In one case the operation was done six hours after the severer symptoms had set in. There was slight improvement at first, and the patient rallied and then died. In the second case the operation was done thirty-six hours after the symptoms of perforation set in; it was also fatal. He would never sanction an operation for perforation in typhoid fever. As soon as he could make out an appendicitis which produced a perforation he gave a bad prognosis.

The Relation of Drinking-water to Disease.—Dr. Henry P. Walcott, of Cambridge, Mass., presented a communication on this subject. The question of the influence of drinking-water in producing disease has not yet been satisfactorily answered. There certainly seems to be a close connection, but it cannot always be proved. The chemical examination of the water is no new thing. It may be chemically impure, and then it is, of course, unfit for consumption; but it may be chemically pure and be just as dangerous, if not more so. Certain pathogenic or disease-producing bacteria live and thrive in water, and these cannot be detected by chemical means. Also water which was so long considered as free from danger has been shown to contain disease-producing bacteria. The principal diseases spread by drinking-water are typhoid fever and Asiatic cholera. The former interests us the most at present. The bacilli of typhoid fever live and thrive in wells—wells and pumps containing water which to the senses is pure have been known to spread the disease to an alarming extent. Numerous instances of this are on record. The refuse of cities has been known to cause typhoid fever in cities below it on the same river, when that city uses the river water for consumption. The State of Massachusetts has appropriated a liberal sum for the investigation of the connection between drinking water and disease, and in taking the towns of Lowell, Haverhill, and Lawrence, it has shown the intimate connection between typhoid fever and the condition of the Connecticut and Merrimac Rivers. There is great need for a more general study of the water of this country.

Contribution to the Pathology of Pernicious Anæmia.—Drs. J. P. Crozier Griffiths, and Charles W. Burr, of Philadelphia, presented a paper with this title. The subject of the causes and nature of the various forms of anæmia was most obscure, yet some system of classification was necessary for the purpose of study. The authors

proposed a provisional definition of anæmia, and a classification of the various forms proposed; reference was made to the published instances appearing to prove the close relationship between various forms of anæmia.

In spite of these seeming objections to the existence of distinct forms, it is probable that some, at least, are entirely distinct; particularly that chlorosis and pernicious anæmia are to be sharply separated. The various theories of the pathology of pernicious anæmia were referred to, and details were given of their own observations upon the presence of iron in the liver, 1st, in several cases of pernicious anæmia; 2d, in various other diseases; 3d, in the case of several animals experimented upon by producing anæmia in different ways.

The following were the conclusions of the authors, based upon their studies up to June of the present year: Pernicious anæmia is a form of hæmolysis, and therefore a non-cytogenic anæmia. In one light the disease, broadly considered, need not be a unity. Thus, a very similar condition can be produced in dogs by the administration of certain chemical substances. Further, patients with bothryocephalus latus, or with atrophy of the gastric mucous membrane, may exhibit symptoms of pernicious anæmia. All these might be considered pernicious anæmia in a broad sense. The same is true of certain cases in which the lavage of the stomach has been followed by the relief of the symptoms of pernicious anæmia. The disease is not, however, to be looked upon as not a unity, or as a symptomatic condition following other diseased states. Tape-worm, putrefaction of the gastric contents, etc., may exist without the symptoms of pernicious anæmia developing.

Pernicious anæmia is rather a distinct affection, which may arise independently, but which may be superadded to chlorosis or any anæmic or other affection. Other anæmias resembling it, but due to any such cause as tape-worm or gastric atrophy, are rather to be considered as other forms of hæmolytic anæmia.

Pernicious anæmia may, then, be defined as an extreme and increasing anæmia, without marked loss of flesh, secondary to no known anatomical lesion, but due to the entrance into the blood of some certain hæmolytic agent whose origin is unknown, but which may be of the nature of a ptomaine.

Changes in the Red Corpuscles in the Pernicious Anæmia of Texas or Southern Cattle Fever.—Dr. Theobald Smith, of Washington, D.C., presented a paper with this title. In 1889 he called attention to certain bodies within the red blood-corpuscles of cattle affected with Texas or Southern fever. After more extended study, including over fifty cases, he had found these bodies always associated with the disease. They are very likely parasitic protozoa, as they appear under several forms and exhibit amœboid movements on the warm stage. At the same he pointed out as the most striking feature of the disease a rapid reduction of the number of red corpuscles, which in many cases fell from a normal of 5.5 to 6.5 millions in a cubic millimetre to one million and less. The presence of the parasites in enormous numbers, and this great reduction of corpuscles seem to stand in the relation of cause and effect. During the repeated examination of blood from each case under observation, the decline in the number of corpuscles was invariably followed by certain changes in the corpuscles themselves. These changes consisted in an increase in their diameter, and in the appearance of a variable number of granules within them, visible only after staining with basic aniline dyes (methylene blue). These "punctuated corpuscles," as he had provisionally called them, appear when the reduction has reached a certain point, and increase in number as the decline goes on, until finally hæmatoblasts appear. At this point the disease usually terminates fatally.

The paper was limited to a description of their changes and a discussion of their nature, significance, and diagnostic value. In presenting this particular phase of the Texas fever investigations, he desired to make them available in the study of the various forms of pernicious anæmia in the human subject, the etiology of which is involved in obscurity.

Dr. William H. Welch, of Baltimore, was particularly pleased with Dr. Smith's paper. It was of great interest, and showed that all medicine is one study, and that the disease in animals and man is scientifically the same. The only difference is the dignity. The protozoa described by Dr Smith act much as the organisms of malaria by getting into the blood-corpuscle and destroying it. The same kinds of blood-corpuscle as he described are to be found in human beings in some forms of anæmia. That this is all one process is not so clear to him. The same changes are observed in the blood in anæmia due to venesection.

Fourth Day, Friday, September 25th.

The Condition and Prospects of the Library of the Surgeon-General's Office, and its Index Catalogue.—Dr. John S. Billings, of Washington, D. C., said the question had often been asked what was the scope, present condition, etc., of the library of the Surgeon-General's Office. He could best answer those questions by giving a few statistics. There were 102,500 volumes in the library, and 152,000 pamphlets, by which he meant those publications of less than 100 pages. From July 1, 1886, to June 30, 1891, he had received 25,337 volumes and 55,900 pamphlets, or about 5,000 volumes and 11,000 pamphlets a year. About 2,000 to 5,000 came from the publishers annually. One-fifth of the library has been presented and four-fifths bought. It is the largest medical library in the world, and it increases faster than the population in proportion. Contains ninety per cent. of the literature published. It has defects. Many old books wanted! Has a good current library in all languages and from all nations. Old books cost so much, and the trouble to search for them through a large number of catalogues makes the books too expensive. The librarian and assistants are not mere functionaries, but show a great interest and love for the work, or it would not be so successful as it is. Twelve volumes of the Catalogue have been printed, and Volume XIII. is in press and manuscript for two more has been prepared. The trouble and care necessary to making a Catalogue can never be appreciated. Books are catalogued by letter two or three times, and also by authors. As the Catalogue goes on new material comes in, so that when the Catalogue is completed there will be enough matter for several volumes of Appendix. A few errors have been discovered, about fifty in the first volume. The "Index Medicus" should be mentioned in this connection. It is a labor of love, and is published through the liberality and generosity of Mr. George S. Davis, of Detroit, the receipts barely meeting the expense of publication. In 1890 there were four hundred and eighty-two subscribers, most in this country and many in foreign countries. The future prospects of the library are excellent. The more it is known the more it is used. Many volumes are unbound because the present laws compel all binding to be done at the Government Printing Office, which is totally inadequate to do so much work. It is to be hoped that these laws will be changed and the binding can be done in the library building itself.

Dr. W. T. Gairdner, of Glasgow, remembered with pleasure Dr. Billings's visit to Glasgow many years ago, and how he took back to America with him what looked to be a mass of unsorted rubbish, but which, under Dr. Billings's orderly hand was soon arranged in its proper place.

Sequel to a Case of Slow Pulse.—Dr. D. W. Prentiss, of Washington, D. C., presented some further details concerning a case previously reported to the Association under the title of "Case of Remarkably Slow Pulse." The patient was brought before the meeting on two successive

years—1889 and 1890. From May 24, to July 2, 1890, the symptoms continued as previously mentioned. The pulse ranged from 13 to 21 per minute, with frequent spells of syncope; toward the last almost constant delirium, and for the last few days he wandered restlessly about the house in constant fear of being shot. July 4, 1890: More delirious and restless than usual; thought several parties were trying to kill him. Screamed with terror, "Murder, fire," etc., until the neighborhood was alarmed. Finally was induced to lie down on the bed. His wife left him for a few minutes, and on returning found him dead. When the pulse was the lowest, these attacks of syncope would be worse. He had no apparent disease of the heart or of the other organs. It was functional slow pulse, and was a very unusual case. He thought there were very few such cases on record until he went to the library, where he found, to his surprise, ninety-three cases under that heading, and many under other headings.

Autopsy of a Case of Slow Pulse.—Dr. R. T. Edes, of Washington, D. C., presented the report of the post-mortem findings in a case of this nature. The sympathetic and vagus nerves on both sides, and the cardiac plexus, were examined with negative results, except that on the left side where the recurrent laryngeal turns round the aorta and gives off cardiac branches there were some slight fusiform enlargements. The microscopic examination of the nerves and of the medulla oblongata will be given. The heart itself was slightly enlarged, but not fatty or dilated.

Dr. W. H. Welch, of Baltimore, asked of Dr. Edes if he examined the nerve in question with one on the other side, because enlargements are to be found on all nerve ganglia, and these are not constant, and sometimes the ganglia are spread along exactly as described by Dr. Edes.

The Effect of Pilocarpine on the Color of the Hair.—Dr. D. W. Prentiss, of Washington, D. C., showed some specimens illustrating the effect of pilocarpine on the hair. This was a young woman with light brown hair. He had been giving her one sixth grain two or three times a week for six weeks. Her hair changed from light brown to dark brown, or from dark brown to black. Lately he had another case somewhat similar. She was an old lady of sixty-eight. He gave the fluid extract of jaborandi. He noticed that her eyebrows turned from gray to black, and one lock of hair, which was white, turned a dark brown; the rest began to turn when she died.

Grave Forms of Purpura Hæmorrhagioa.—Dr. J. H. Musser, of Philadelphia, read a paper on this subject. He divided all cases into idiopathic and symptomatic, and reported several fatal cases—cases with joint complications and ulcerations, and cases with œdema and sloughing of the skin of the scrotum, penis, etc. He made a report on the negative results of the bacteriological examination in one case, and described a coccus much like the staphylococcus pyogenes aureus.

Dr. W. H. Welch, of Baltimore, thought that the coccus described by Dr. Musser was the ordinary skin coccus, which is found sometimes deep in the skin, as the methods of cleansing as described by Dr. Musser were not sufficient to destroy this organism.

Dr. William Pepper, of Philadelphia, referred to two cases of purpura in his own practice in which there was extensive sloughing, and in both cases there was complete suppression of vision in the left eye. He had had also two cases of rötheln, which disease was endemic in Philadelphia just after the influenza. In both cases there was extreme hemorrhage with fever—105° F. to 106° F.—followed by sudden recovery.

Dr. D. W. Prentiss had presented a case last year to the Society, and the result was the cure of the case. The lung had frequent and prolonged hemorrhages, which did not yield to large doses of arsenic. He brought him before the Society, and at its suggestion used phosphorus, with a cure as the result. The boy owed his life to the Society.

Dr. J. E. Graham, of Toronto, had used the phosphide of zinc, but not phosphorus; was glad to hear of its advantages, and would use it.

Dr. Theobald Smith, of Washington, D. C., had examined the blood in Dr. Prentiss's case and remembered having found tinted corpuscles.

Bradycardia in Acute Articular Rheumatism.—Dr. I. E. Atkinson, of Baltimore, presented a communication on this subject. Bradycardia, or unduly slow heart-action, he said, is a symptom observed in a variety of disorders apart from those in which there is manifest disturbances of the central nervous system. It is not infrequently observed during convalescence from acute febrile disease, when it disappears, usually with the re-establishment of health. Much more uncommonly it develops at the outset or during the active period of such disease. It is thus rarely observed during an attack of acute articular rheumatism; more often, but still quite infrequently, it occurs during convalescence from acute articular rheumatism. In the former case it probably depends upon pericarditis or endocarditis, whereby the innervation of the heart is impaired. In the latter case it is probable that in some instances it is still due to these causes, though it may also depend upon the same influences that excite it during convalescence from other acute specific febrile diseases, and which are apparently not inflammatory.

Dr. H. P. Bowditch, of Boston, said there were two sets of nerves to the heart, one set inhibitory, and one stimulating. Paralysis of the stimulating nerves might produce these effects. It was hard to say whether we have to do with a paralysis or a stimulation. We cannot say that the same nerve fibres exist in men as we know exist in animals, although this is probable.

Dr. William T. Ord, of London, thought that robust, stout people usually had slow pulse, due, he thought, to weakening of the whole system, or nervous system in particular. There is slow pulse in rheumatism when the temperature is somewhat high. Thinks that the pneumogastric nerves play an important *rôle* in rheumatism.

Dr. I. E. Atkinson, of Baltimore, thinks it is a stimulating influence, but this is purely an idea.

AMERICAN ASSOCIATION OF ANDROLOGY AND SYPHILOLOGY.

Fifth Annual Meeting, held at the Shoreham Hotel, Washington, D.C., September 22, 23, 24, and 25, 1891.

(Continued from p. 384.)

Third Day, Thursday, September 24th.

Hæmaturia.—Dr. W. K. Otis, of New York, read a paper with this title, in which he stated that the diagnosis of hæmaturia usually offers no great difficulties; the mechanism of micturition, chemical examination of the urine, instrumental exploration of the bladder, and, finally, the resorption test, furnishing sufficient points for diagnosis. If the locality of the hemorrhage is in the anterior urethra, the blood will flow continuously; if it is situated in the posterior urethra—the pars prostatica—the flow of blood will not be continuous. The urine itself will be clear. If the point of hemorrhage is in the interior of the bladder, the blood is intimately intermixed with the urine. Blood-clots in the urine—the long coagula, like worms—indicate renal hemorrhage, representing casts of the ureters. If the coagula are short and broad, they originate in the bladder. If the specific gravity of the urine is low, renal hemorrhage is indicated; on the other hand, if it is normal or high, vesical hemorrhage. Vesical hemorrhage is also indicated when ammoniacal fermentation is present. If the microscope reveals casts containing blood-corpuscles or hyaline casts, the hemorrhage is from the kidney; if only vesical epithelium is

found, the hemorrhage is from the bladder. When the examination of the urine is negative, instrumental examination of the bladder and the resorption test are usually conclusive. Before making the instrumental test the bladder should be thoroughly washed out; then, when the catheter is moved about, the bleeding will immediately commence anew if the point of hemorrhage lies in the bladder. The resorption test is made with a solution of potassium iodide, which is injected into the bladder by means of a soft catheter. It is an established fact that if iodide of potassium is brought into contact with a point capable of resorption, iodide can be demonstrated in the saliva after a very short time—not more than fifteen minutes, and in hæmaturia this indicates that the hemorrhage is from the bladder. When the bleeding is not too profuse, the electro cystoscope is of great value in establishing a positive diagnosis.

Dr. Taylor stated that Dr. Otis might add to his paper a fact he already knows, and that is, that in severe cases of urethritis a little blood might flow from the anterior portion of the urethra, due to the contractions of the muscular fibres upon the mucous membrane.

Dr. Bryson stated that he had seen many cases of renal hemorrhage where the specific gravity of the urine was still high, and remained fairly so. Sometimes different layers of urine in the bladder were of different specific gravity, and he considered it best not to lay too much stress upon that point.

Clinical Notes on (*a*) Hypertrophy of the Prostatic Sphincter; (*b*) Relation of Rectal Distention to Arterial Depression.—Dr. William T. Belfield, of Chicago, read a paper with this title. He stated that hypertrophy of the prostatic sphincter, occurring secondarily to vesicle irritation from stone, etc., is a well-known condition; but that occurring as an apparently independent affection, without discoverable antecedent morbid changes, it is less generally recognized. Dr. Belfield then gave the history of two patients, one aged nineteen and the other twenty-seven, upon whom he had operated within the past year and discovered a hypertrophied condition of the prostatic sphincter. The author closed his paper by suggesting whether in these cases there may have been an antecedent morbid condition in the bladder, and whether this hypertrophy of the prostatic sphincter may not be a frequent cause of vesicle irritability. In his second paper Dr. Belfield stated that at a previous meeting of the Association he had mentioned the fact that irritation of the mucous membrane of the rectum in dogs produced a decided arterial depression, amounting sometimes to fifty per cent. Since then he had noticed that in operations upon the bladder, or other operations where the rectal bag was employed, there was a marked lowering of arterial tension, which disappeared when the bag was withdrawn.

Notes on the Surgery of the Prostate.—Dr. Wishard, of Indianapolis, in a paper on this subject, stated that bladder surgery, particularly in more recent years, suggests the following principles: First, that a large percentage of cases of prostatic cystitis which are not susceptible of relief by palliative treatment can be more or less permanently relieved by surgical interference. Second, that perineal and suprapubic incisions are the two methods best calculated to accomplish the results sought. Third, that neither one of these operations is suitable in all cases, and that both may sometimes be required. Fourth, that the objects of radical operation should be the removal of the mechanical obstruction and to secure rest and drainage for the bladder. Dr. Wishard then gave some of the advantages of the various methods of operation employed in these cases, and said that the fact must be borne in mind that at the time many prostatics apply for treatment the mechanical obstruction is by no means the most serious condition present. Resulting renal disease, loss of muscular power, and thickening and diminution in the size of the bladder render more or less futile both palliative and radical efforts at relief in such cases.

The two preceding papers were discussed together.

Dr. J. Blake White, of New York, said that a short time ago a patient came under his care who manifested very distressing symptoms of vesical irritability; the bladder and right ureter were made out to be in a dilated condition. Suprapubic cystotomy was performed, and the prostatic sphincter was found to be retracted. The sphincter was dilated with the finger, drainage was kept up for fifteen days, and the patient made a satisfactory recovery.

Dr. John P. Bryson, of St. Louis, stated that he considered the two papers just read both interesting and instructive. Dr. Belfield, some years ago, had called attention to the fact that irritation about the vulva, genital organs, and rectum lowered the blood-pressure. Dr. Bryson did not consider this failure of the heart which follows operations about the bladder as merely a mechanical affair, but as a general nervous disturbance, perhaps in some way allied to urinary fever, and as something which must be guarded against by the surgeon.

Dr. W. K. Otis, of New York, stated that last year he reported a case in which a tumor of the prostate was removed, about the size of the end of a man's thumb, and eight ounces of residual urine were withdrawn. It is now about eighteen months since the operation, and the patient is in perfect health. Dr. Otis said that he had passed a catheter the other day and found no residual urine in the bladder.

Observations upon the Surgery of the Ureter.—Dr. Arthur T. Cabot, of Boston, presented a communication on this subject. These observations, Dr. Cabot stated, were the result of some investigations upon the anatomy of the ureter with reference to its surgical accessibility in different parts of its course, and with the especial object of determining how best to reach and remove impacted stones in the ureter. The author takes it for granted that, if possible, it is always best to use the extra-peritoneal incision for the removal of a stone. Dr. Cabot stated that the search for the ureter is much simplified by a knowledge of the fact—which he does not find mentioned in any description of its anatomy—that it is in relation with that part of the peritoneum which becomes adherent to the spine. After the ureter dips down into the pelvis it is not so easily located, because it does not bear any fixed relation with a bony landmark, but, fortunately, in the cases in which a stone is sought in it, we have a hard body that is readily felt to guide us to it. To reach the ureter in the upper part of its course, Dr. Cabot said, perhaps no better incision can be chosen than that planned by Israel. He draws a line from a point on the anterior edge of the sacro-lumbar mass of muscles, just below the twelfth rib, and parallel to it; then turns downward toward the middle of Poupart's ligament to the line of incision usually made for tying the iliac artery; then again turns toward the middle line and ends on the external border of the rectus muscle. According to the location of the calculus, the incision can be made on the posterior, middle, or anterior third of this line.

Dr. William T. Belfield, of Chicago, stated that while he had had no personal experience in connection with surgery of the ureter, he had had occasion to expose the base of the bladder, and could see the advantages of the incision suggested by Dr. Cabot. He desired to express his obligations to Dr. Cabot for his admirable paper.

Exhibition of Complete Double Ureters of Both Kidneys.—Dr. Edmund E. King, of Toronto, presented specimens of complete double ureters of both kidneys. Dr. King said that in ten post-mortem examinations made by him he had found three cases of supernumerary ureters.

The Dry Poultice in the Treatment of Epididymitis.—Dr. George E. Brewer, of New York, read a paper with this title. The object of his contribution, Dr. Brewer said, was to call attention to a method of treatment which he has found especially useful in the manage-

ment of gonorrhœal epididymitis, and which, although considerably employed in France, has not yet received much attention in this country. This method of treatment is a simple dressing, consisting of a moderately thick layer of cotton-wool applied over the inflamed testicle and covered by a layer of thin rubber protective tissue, so as to completely enclose the diseased organ and overlap the healthy skin of the scrotum. This is snugly secured by a gauze bandage, and the whole held in place by a suspensory. Such a dressing, the author stated, meets all indications in cases of acute epididymitis; the pain is speedily relieved, and there is rapid absorption of the inflammatory induration.

Dr. John P. Bryson, of St. Louis, said that he was greatly interested in Dr. Brewer's paper, and especially where it referred to the rapid absorption of the inflammatory induration. He wished to inquire whether this method of treatment caused the disappearance of those little fibrous nodules, or lessened their number.

Dr. James P. Tuttle, of New York, asked how much pressure should be applied in bandaging the testicle.

Dr. Brewer stated that he had not noticed the disappearance of the fibrous nodules referred to by Dr. Bryson. His cases were dispensary patients, and soon lost sight of. In answer to Dr. Tuttle's question, Dr. Brewer said that only a moderate amount of pressure was required.

Fourth Day, Friday, September 25th.

On the Radical Cure of Urethral Stricture by Restoration of the Mucous Membrane to a Healthy Condition, by Dr. John P. Bryson, of St. Louis. Stricture of the urethra, Dr. Bryson said, is a chronic contracting periurethritis, caused by the leakage of urine or some of its constituents through a damaged or absent mucous membrane. This pathological definition enables us to accept a more definite and better classification of strictures, and appears more available than that of Vollmemier, which divides them into inflammatory and cicatricial, the first being still lined by mucous membrane, damaged though it be, the last by none at all, the mucosa having been replaced by cicatricial tissue. Any therapeutic procedure, therefore, Dr. Bryson stated, must primarily aim at a restoration of the mucous membrane to the normal state, and this is exactly what surgeons of to-day are doing in so many cases with most flattering success. The author stated that his entire treatment of stricture was based on the theory that if the mucosa could be restored to a normal condition while the stricture band was undergoing softening and inflammatory involution, a radical cure could be hoped for. Linear strictures, Dr. Bryson said, are often permanently benefited by the use of the sound only, but he considers this method entirely inadequate in the case of annular strictures. He then gave the history of a case of annular stricture which was treated by cutting and divulsion a number of times with only temporary relief, and which was radically cured by intermittent dilatation, combined with topical treatment directed to the restoration of the lining mucous membrane.

Treatment of Urethral Stricture, by L. Bolton Bangs, of New York. Dr. Bangs defined stricture of the urethra as an unnatural narrowing of the urethral canal in any part of its entire length. That portion of the urethra described by anatomists as the bulbous portion is the largest in calibre, both in the adult and in infantile life, and is capable of the greatest amount of physiological distention. Dr. Bangs stated that he desired to reaffirm his belief in the principle formulated by Dr. Otis, namely, that the human urethra bears a proportionate relation to the size of the penis in which it is contained, and that this fact must be recognized in order to determine how to give radical and humane treatment for an infirmity which concerns so many. The treatment of strictures by divulsion, the author said, he considered both non-surgical and non-scientific. The effect of the instrument is distributed more or less beyond the strictured area, and the resulting cicatrix is an irregular and ofttimes a violently contracting one. Electrolysis, also, he does not approve of. Where a sufficiently strong current is employed to have any effect upon the tissues at all, it acts as an irritant and produces inflammatory deposits. Dr. Bangs regards gradual dilatation as sufficient for soft non-fibrous strictures of the posterior urethra or in the bulbous or penile portion, but for all strictures of large calibre requiring interference he advocates treatment by internal urethrotomy and complete division. If the stricture is of small calibre, or be complicated by fistulæ, either in the penile urethra or perineum, or if there be indurated cicatricial deposits posterior to four and one-half inches, he advocates, in connection with internal urethrotomy, an external perineal urethrotomy also, and combined with prolonged perineal drainage.

The Treatment of Urethral Stricture and Its Resulting Conditions by Extreme Gradual Local Distention and Without Cutting; Including a Brief Résumé of Fifty Cases.—Dr. James P. Tuttle, of New York, read a paper with this title, in which he said that perhaps the best practical definition of stricture was that recently given by Dr. White, in the words "Stricture is an abnormal lessening of the calibre or the dilatability of the urethral canal, associated with changes in the mucous, muscular, or submucous structure constituting its walls" As to the question so frequently discussed, What are the normal constrictions of the urethra and what relation do they bear to its normal calibre? Dr. Tuttle said that he has made measurements of the dilated mucous membrane in fifty cadavers and in more than one hundred living subjects; these observations were made upon healthy urethræ and in all cases certain constrictions and dilatations were found, all more or less uniform and no doubt perfectly normal These he considers natural anatomical conformations and they demand from the surgeon careful consideration and conservatism. The author said that he practised internal dilating urethrotomy for eight years, but that recently he abandoned the cutting process in most cases and substituted treatment by extreme local distention, that is, at the strictured spot only. With this object in view Dr. Tuttle has devised a new instrument, called a urethral dilator, which he has used for some time and with which he has obtained good results in these cases.

The three foregoing papers were discussed together.

Dr. Robert W. Taylor, of New York, stated that the profession is apt to run to extremes in the treatment of strictures. To Dr. Bangs, the speaker said, is largely due the credit of introducing perineal urethrotomy, which is a most admirable and beneficial procedure in certain cases.

Dr. W. K. Otis, of New York, said that in cases where the strictures were situated in the posterior urethra, and surrounded by hard, cicatricial deposits, it seemed useless to try to remove them by any but the surgical method of external urethrotomy.

Dr. John A. Fordyce, of New York, said that he considered Dr. Bryson's definition of stricture—a chronic contracting peri-urethritis—as an excellent one, but that in his opinion it did not always depend upon an infiltration of urine; that in some instances it was caused by the entrance of the gonococci (or the chemical products they give rise to) into the glandular or epithelial tissues.

The discussion of these papers was continued by Dr. L. Bolton Bangs, of New York; Dr. Bryson, of St. Louis, and Dr. Palmer, of Louisville.

Treatment of Gonorrhœa, by Dr. W. Frank Glenn, of Nashville. In his paper Dr. Glenn said that he has met with great success in the treatment of gonorrhœa by the use of mild solutions of chloride and iodide of zinc. The strength he usually employs is one-half grain of the chloride and one grain of the iodide to the ounce of water. This solution can be further diluted if necessary, and is to be injected into the urethra three or four times daily.

Dr. Taylor stated that the personal element entered very largely into the treatment of gonorrhœa, and a second person cannot always obtain such good results by following the same course of treatment. Chloride of zinc he considered very useful in some cases, in the declining stages of urethritis, but he would be very loath to use it for deep injections. The iodide of zinc he has never used.

Dr. William Judkins, of Cincinnati, stated that he has had considerable success in certain cases by applying on a sound, the yellow oxide of mercury, or introducing it into the urethra on a small piece of cotton.

Dr. L. Bolton Bangs, of New York, stated that he coincided with what Dr. Taylor had said about the personal element in the treatment of gonorrhœa—not only of the physician, but of the patient also. Dr. Bangs said that he was ready to welcome any remedy that will shorten the period of the disease.

Dr. Otis said that salol was recommended for gonorrhœa at last year's meeting. He had given the drug an exhaustive trial, and had seen nothing produced excepting a little dark-colored urine.

Adjourned.

AMERICAN ORTHOPEDIC ASSOCIATION.

Fifth Annual Meeting, held at the Arlington Hotel, Washington, D. C., September 22, 23, 24, and 25, 1891.

(Continued from p. 386.)

Third Day, Thursday, September 24th.

Malignant Disease of the Spine Simulating Pott's Disease.—Dr. Judson reported three cases, in which Pott's disease and malignant vertebral disease had been confounded by himself and other observers. The first patient, a boy of four years, died three months after the appearance of symptoms. The other patients, men, aged respectively thirty-five and forty-two years, survived the first symptoms one or two years. In each case an autopsy was made correcting the ante-mortem diagnosis in two cases, and confirming it in one. In no case was there distinct kyphosis. In two cases there was paraplegia, the paraplegia dolorosa of malignant disease and not that of Pott's disease. The chief symptoms were general prostration, and pain and disability located in the back. These patients were very ill, which cannot well be said of most patients affected with Pott's disease. They had severe pain and extreme disability in the back, which Pott's disease is so free from that when we hear of pain in the back and spinal disability the first thought is to eliminate spinal caries. In brief, the chief diagnostic points are, 1, deformity, present in Pott's, absent in malignant, disease; 2, local disability; and 3, local pain, both absent in Pott's and present in malignant disease.

Prognosis of Pott's Disease.—Dr. Samuel Ketch, of New York, considered the prognosis from the following stand-points: 1, region; 2, age; 3, etiology; 4, complications; 5, thoroughness of treatment. Seventy-five cured cases were considered. In the superior region, first cervical to third dorsal, the average time of treatment for obtaining a cure was $26\frac{1}{5}$ months. In the middle, third to tenth dorsal inclusive, $64\frac{1}{2}\frac{8}{5}$ months. In the inferior, tenth dorsal to fifth lumbar, $47\frac{1}{5}\frac{1}{5}$ months. Twenty-eight cases presented for treatment were from one to five years of age; 31, from five to ten years of age; 16, above ten years of age. Seven cases gave unmistakable evidence of traumatism as a cause. These required a much shorter period of treatment than the remaining 68, sixty per cent. of the total number. The latter, as a rule, gave evidence of a tubercular diathesis. Abscess was frequent in the middle and inferior areas, nearly fifty per cent. developing them during the course of the disease. Treatment must be carried out over a long period of time in order to obtain good and permanent results; the tendency to early removal of apparatus is to be deprecated. Under thorough mechanical treatment abscess is frequently prevented, and when present often disappears. While it is known that recession of deformity has occurred in some cases, no positive statement could be made about this point. As a rule, slighter deformities could be prognosticated in the superior and inferior than in the middle area, where the deformity, as a rule, attained its largest growth. Paraplegia may be looked for more frequently in the superior and middle regions, rarely in the inferior.

Proposed Treatment of Pott's Disease by Wiring the Vertebral Processes.—Dr. B. E. Hodra, of Galveston, Tex., said that wiring of the vertebral processes would secure firmness of the column, forming a posterior brace to the parts needing immobilization, thereby securing rest to the diseased vertebræ. The bodies where the chief trouble is located will by leverage be removed from each other, and their rubbing and pressure on each other be avoided. The operation would seem to be most desirable when the first symptoms of deviation appear. If large abscess cavities have formed already, it may be safer to allow the vertebral bodies to come into close contact. The speaker believed that there was practically no danger in the operation, and that it would shorten the tedious treatment by braces.

The Operative Treatment of Tubercular Caries of the Spine.—Dr. De Forest Willard, of Philadelphia, divided operative treatment for this disease into three divisions: 1, for pus accumulations; 2, for the removal of carious bone; 3, for the relief of paraplegia.

His conclusions were: 1. Recumbency, extension, mechanical support of the diseased vertebræ after anchylosis has resulted, are exceedingly important preventions of and additions to operative procedures. 2. Dormant and caseating foci may well be treated on the expectant plan. 3. Liquefaction and caseating collections should be tested with the aspirator and injected with iodoform emulsion; the operation being repeated unless pus is discovered. 4. If sero-purulent fluid is drawn, injections may still be relied upon to assist the system in conquering and limiting the tuberculous process. 5. When true pus is present, the abscess should be incised, the cavity washed out by a long-continued flow of hot sublimate solution, but manipulation should not be practised upon the walls of the sac, lest a fissure be occasioned and entrance of tubercular poison into the system be facilitated. The incision should be carefully sutured, and from thirty to sixty grains of iodoform injected and retained in the cavity. 6. When the situation of the abscess is in the lumbar region and the case permits, the sac should be thoroughly removed. 7. Drainage-tubes should not be retained longer than necessary. 8. When excision of the wall is impossible, free incision and drainage, coupled with iodoform injections, are palliative. 9. Excision of diseased bone tissue is feasable only when it is situated in the arches. Removal of laminæ for the relief of pressure paralysis is only to be employed after a thorough trial and failure of long-continued horizontal extension, counter-extension, and fixation; and where the pressure is posterior to the cord.

The Operative Treatment of Spastic Paralysis.—Dr. W. N. Bullard, of Boston, read a paper on this subject by Dr. Charles L. Scudder, with remarks by himself on the nervous phenomena of the case of paraplegia reported. So far as is at present known, the causative lesion is of the central nervous system in the motor tract. Treatment by drugs, electricity, and operations on the cerebral lesion have failed. Apparatus applied to the limbs, no matter how well fitted and carefully managed, accomplishes nothing permanent. In the opinion of Dr. Bullard, practically all cases of spastic paraplegia in children not due to transverse myelitis are of cerebral origin. The case reported had hydrocephalus and a spina bifida, and Dr. Bullard shows by conclusive reasoning that the cerebral, and not the spinal, complication must be considered as the cause of the spastic paraplegia in this case.

Treatment of Pott's Disease, with Especial Reference to the Early Stage.—Dr. Bernard Bartow, of Buffalo, said that when treatment is begun in the early stage of

vertebral osteitis, therapeutic agents are of greater efficiency than in any subsequent stage of the disease. The pathological conditions in the early stage favor this view. The focus of the disease is small; the form of the vertebral body is unchanged; and neural disturbances are of a modified type. Restraint of movement favors encapsulation of the focus of the disease. Complete arrest of the disease occurs without angular deformity in a large percentage of cases by appropriate treatment. The period of treatment is shorter by at least one-half. Prognosis is greatly modified, owing to the rarity of abscess, paraplegia, and secondary infection. Functional exercise acting upon the diseased bone, is the agent which is chiefly instrumental in favoring the extension of the disease, by the invasion of new tissue. Reflex muscular contraction is much less prominent in the early stage, and spinal distortion must be chiefly depended upon for the diagnosis. Treatment is by the use of a jacket of some plastic material, made upon a corrected cast of the patient's body made during suspension.

Pott's Disease in Middle and Advanced Life.—Mr. Howard Marsh, of London, related a number of cases of disease of the spine in old people, and said in conclusion that he regarded them as examples of tuberculous disease rather than osteo-arthritis, for the following reasons: 1. These patients did not present that disease in any other part. 2. I am not aware that osteo-arthritis produces angular curvature. 3. Many of these cases suppurated, a result very rare in osteo-arthritis. 4. So trustworthy an observer as Sir James Paget states that he has himself met with tuberculous disease of the spine in old subjects. 5. There can be no doubt that tuberculous disease of other parts is by no means very rare in the old. 6. These cases are exactly similar to cases of tuberculous disease of the spine as we see it in the young.

Cervical Spondylitis.—Dr. L. A. Wiegel, of Rochester, reported the case of a boy eight years of age, who for two years suffered from paralytic symptoms, which compelled him to retain the recumbent posture. He was unable to sit up, even for a few seconds, without intense pain in the head. A retro-pharyngeal abscess developed in the course of the disease. The treatment by recumbency, combined with traction by means of weight and pulley, gave prompt relief from pain and rapid improvement of the paralytic symptoms.

Recumbency in the Treatment of Pott's Disease.—Dr. A. Morgan Vance, of Louisville, said that some cases, in spite of any brace, would continue to have pain, have lateral deformity, would not tolerate head support, or whose parents would not conduct the brace treatment properly. Such cases should be treated by recumbency, and invariably do well. In no case has any injurious effect been traceable to the recumbency.

Extension in Bed in the Treatment of Caries of the Spine.—Dr. C. C. Foster, of Cambridge, Mass., said that extension was applicable in caries of all parts of the spine, but was especially useful in caries of the cervical region. It reduces deformity, pain, inflammation, and liability to abscess. It makes the disease less exhausting, shortens its duration, and minimizes the amount of repair demanded. Extension is obtained by small weights, the cords running over the head and the foot of the bed, and attached to waist-belts, chest-belts, or Sayre head-straps. Such treatment cannot be carried out in out-patient and tenement-house cases. It is however the ideal treatment during the active stage, and no ill effects will be observed from the prolonged confinement in bed.

Fixation and Traction in Pott's Disease.—Dr. R. H. Sayre, of New York, divided the sources of trauma to the spine into: 1, super incumbent weight of the body above the point of disease; 2, concussion; 3, reflex muscular spasm; 4, movement. It is necessary to avoid all injury and irritation of the diseased part. The essentials of treatment are traction to the point of comfort and fixation of the diseased area. In the acute stage of some cases recumbency may also be necessary, but it is better to combine an out-of-door life with the treatment if possible. Recumbency alone is not enough. The posterior spinal splint combined with recumbency fails to counteract the reflex muscular spasm, for which traction is demanded. The straps and aprons of these splints also restrict respiration.

The plaster jacket can be made to fit better if made directly upon the patient than if made upon a cast. Jackets that are not properly shaped about the waist, so as to be supported from the hips, are most objectionable, inasmuch as they not only fail to give the needed traction, but because the weight of the jury mast and jacket by slipping down is added to the weight of the patient's head and bears upon the diseased spine. An amusing case was referred to, where an orthopedic surgeon placed a cushion upon the child's head to receive the weight of the jury-mast and jacket, which should have been supported from the hips, and in its turn should have supported the head and relieved the downward pressure upon the point of disease. In very small children the wire cuirass and jury-mast are used. In paraplegia traction combined with strong counter-irritation are advised.

Comparative Value of the Prevalent Methods of Treatment of Caries of the Spine.—Dr. E. H. Bradford, of Boston, grouped the methods of treatment as follows: by recumbency; by mechanical appliances; and by plaster bandages and corsets. Of that by recumbency, it may be said to be of great value in the acute stage, and where there is great disability in getting about, disinclination to walk and run, and more contentment when lying or sitting. The patient should be kept on his back with a proper arrangement of pads, and fixed by straps so that no sitting up or turning in bed is possible. It should be arranged so that the patient can be carried about freely, and receive the benefit of open air. Traction may at times be added with great assistance. This is the most efficient way of preventing increase of the curvature; but it cannot be continued till the cure is effected. When general nutrition begins to fail after a long period of recumbency, it should be discontinued. Mechanical appliances are an essential part of the treatment of every case at some stage of the disease, to enable the patient to go about without danger. The mechanical appliance which has been found most useful has been based on the principle of the antero-posterior leverage brace. Where head supports are necessary, the jury mast, the wire support, the Thomas collar, or the Taylor oval ring, are used. Where the surgeon possesses the requisite skill and experience and the parents will give proper attention, mechanical appliances furnish the most efficient means of treatment. The permanent plaster jacket should be used where great care cannot be given by the parents. All plans mentioned may, in any given case, be required severally in the course of the treatment.

Fourth Day, Friday, September 25th.

A Further Contribution to Typhoid Spine.—Dr. V. P. Gibney, of New York, related the case of a man forty-five years of age, who, twenty-two years ago, had typhoid fever followed by pain in neck and back of head, and later down the arms. After a few weeks the pains subsided, but he has remained with a prominence in the cervico-dorsal region and a torticollis.

A Brief History of the Use of Suspension in Pott's Disease.—Dr. Benjamin Lee, of Philadelphia, gave a history of suspension and traction in Pott's disease and other spinal affections, from the time of Hippocrates to the present day, and showed that the credit for having devised this plan of treatment is not due to Professor Sayre, as is generally supposed, but that it was practised most enthusiastically centuries ago. To Dr. J. K. Mitchell, of Philadelphia, belongs the credit of having, in 1826, introduced into this country this treatment of Pott's disease; and to Dr. Lee should be accredited the honor of having first used self suspension in the treatment

of Pott's disease, lateral curvature, spinal pressure, paralysis, and the condition known as spinal irritation. Dr. Lee's first paper was in 1866; since which many subsequent writings on the subject have been published. By a letter, written May 17, 1877, Professor Sayre acknowledges that the credit is due to Dr. Lee.

The Treatment of Congenital Dislocations of the Hip.—Dr. E. H. Bradford, of Boston, showed photographs of appliances for the treatment of a case of double congenital dislocation of the hip-joint, which, for the last three years, had been treated according to the method of Dr. Buckminster Brown. The modifications from Brown's method were such as to allow the patient to be carried about, but not to stand. At the present time the patient is allowed to walk about, wearing protective appliances such as are used in the convalescent stage of hip disease by Dr. Taylor. These appliances are made of aluminum, and are light. The result so far has been that the trochanter has been brought down from its position upon the ilium three-quarters of an inch, and has remained in this position. The patient is beginning to walk about. There is at present some lordosis, but the lateral gait has entirely disappeared.

On Elongation of the Ligamentum Patellæ as a Factor in the Production of Certain Knee Troubles and Difficulties in Locomotion.—Dr. Newton M. Shaffer, of New York, reported a number of unique and interesting cases where the patellar tendon had become elongated from various causes.

Observations on Torticollis, with Particular Reference to the Significance of the So-called Hæmatoma of the Sterno-mastoid Muscles.—Dr. Royal Whitman, of New York, said that from a review of the literature and clinical observations he had concluded that congenital torticollis is usually of intra-uterine origin, and not the result of giving way at birth as stated by many writers. He presented a report on two hundred and sixty-four cases of torticollis, showing that the affection is more frequent in females than males, and the sides of the neck are equally liable, although the opposite opinion usually prevails. Finding that acquired torticollis is often the result of enlarged or suppurating cervical glands, and in such cases not persistent in character, he concludes that the deformity should be treated in the early stage by some appliance which holds the head in perfect position. Such appliances provide rest for the inflamed parts, and prevent the permanent shortening of muscles and fascia which quickly appears in young and rapidly growing children. If the deformity has persisted for more than six months mechanical treatment is usually inefficient, and in these cases free and early division of all contracted parts, with careful after-treatment, is indicated.

Ten Cases of Excision of the Knee-joint.—Dr. Joseph D. Bryant, of New York, reports four cases in detail, six having been previously reported, and considers the lessons which may be learned therefrom. He believes that excision of the knee-joint is admissible for the following conditions: 1. When remote or unsound anchylosis appears to be the only result that can be reasonably expected. 2. When mechanical and remedial measures, faithfully applied, have failed to afford any permanent relief. 3. For vicious anchylosis, or for deformities that cannot be overcome under anæsthesia combined with tenotomy or extension. 4. As a substitute for the expectant plan of treatment, when the unfavorable surroundings of the patients, or the slow course of the disease, make hopeless or even doubtful a recovery with sound anchylosis. 5. When remote or unsound anchylosis appears to be the only means of securing a serviceable limb.

He also pointed out the advisability of operating at once when kidney disease is found to exist, as a presumptive consequent complication.

Apparatus for Making Traction.—Dr. William E. Wirt, of Cleveland, presented a new traction brace of unique design, devised by Dr. Karl von Klein, of Cleveland. The racket and lever are used in principle somewhat similar to the levers of Lagarousse, with the difference that the force of the lever is transformed into rectilinear motion, which, in the levers of Lagarousse, and nearly all the usual forms of racket-levers, is transformed into circular motion. The claims for the brace are: that no key, screwdriver, wrench, buckle, or strap is used to adjust it; that it is easy to adjust and regulate; that it is not bulky, or bunglesome; and that it has a fine adjustment. The form of movement may be adjusted to any form of traction-brace.

Rheumatic Spondylitis.—Dr. George W. Ryan, of Cincinnati, said that the symptoms have a close resemblance to tuberculous spondylitis before the stage of deformity, and unless there be a history of rheumatism, it may not be possible to make the diagnosis sure. There is difficulty in locomotion, rigidity, and pain. Later on the kyphosis appears, but it lacks the angularity of Pott's disease, and more resembles the kyphosis of senility. The prognosis is bad. The treatment should be directed to relieve the pain: a support, local blistering, the Paquelin cautery, and internal medication. One case was reported in detail.

The Definition and Scope of Orthopedic Surgery.—Dr. V. P. Gibney, of New York, read a paper intended to define and to mark out the limitations of the practice of orthopedics. It was in a measure a reply to the paper: "What is Orthopedic Surgery?" by Dr. Newton M. Shaffer, read at Berlin on August 5, 1890. The writer did not wish it to be understood that American orthopedic surgeons limited themselves to the use of splints and straps and buckles. He believed that the orthopedic surgeon should be competent and feel himself free to use any means within the range of operative surgery to bring any case under his care to a successful termination, without help or hindrance from the general surgeon, who did not hesitate to operate upon cases of knock-knee, bow-legs, and club foot, which surely come within the range of orthopedic practice. He pointed out how so many unnecessary relapses occurred as are met with as the result of the work of the general surgeon, and showed it to be because the general surgeon failed to appreciate the necessity for the use of apparatus in the after-treatment, and lacked the knowledge of how to apply this apparatus. He would enlarge the definition of orthopedic surgery and make it read thus: Orthopedic surgery is that department of general surgery which includes the prevention, the mechanical treatment, and the operative treatment of chronic progressive deformities.

Scoliosis in Its Relation to Flat-foot.—Dr. Paul Redard, of Paris, sent a communication, calling attention to the dependence of certain cases of scoliosis upon nasal stenosis, and the relation of so called static scoliosis to flat-foot. In these cases the triangle between the arm and the side is lessened on the side of the lumbar convexity; the posterior-superior iliac spine on that side is lower, the buttock flatter, really or apparently shorter, the inner malleolus lower, and the foot in the position of valgus, and at times a truly painful flat-foot. Statistics of one hundred cases were cited. Treatment should be directed to remedying the flat-foot and correcting the shortening of the extremity, as well as to the correction of the curvature itself.

A Contribution to the Pathological Anatomy of Scoliosis.—Dr. F. Beely, of Berlin, said that traction and pressure, according to the degree, the manner, or the length of time which they may act, may cause an increase or a cessation of the development of the osseous tissue in a vertebra, increasing the horizontal diameter, diminishing the thickness on the side of pressure, and increasing the thickness on the side of traction. At the epiphysis, however, the growth of the bone seems to be affected differently, the proliferation of tissue being generally in the direction of the greatest pressure. The speaker then pointed out the differences between the vertebra of a child and that of an adult. The increase in that of the adult

is in the anterior portion subjected to the strongest pressure, while in the posterior portion—the convex side—a flattening of the vertebræ, including the spinous process, is found when viewed in horizontal projection. The changes there having taken place, the body having become wedge-shaped and changed in its diameters, rotation takes place. As the body rotates while the arch remains fixed, a break occurs in the antero-posterior axis of body and spinal process, and from one it becomes two lines joined in a greater or less angle. The result is that in the dorsal region the *paraspinous sulcus* is very shallow and broad on the concave side, and deep and narrow on the convex side. In the lumbar region we should expect this peculiarity to still hold in its relations to convexity and concavity, but it is not so—the shallow sulcus is here on the side of the convexity, and deep on the side of the concavity. This is explained by the absence of the ribs in the lumbar region.

The Operative Treatment of Deformities Following Infantile Spinal and Cerebral Spastic Paralysis.—Dr. De Forest Willard, of Philadelphia, has operated upon a large number of cases, and he believes that there are but few which cannot be more or less benefited. Even when incapable of walking upon the limbs, artificial support and mechanical appliances following thorough rectification of the deformities, will add greatly to the comfort of the patient. His conclusions were: The deformities of infantile paralysis can be prevented by apparatus, but if this has been neglected and distortion has occurred, secure the best possible limb by immediate surgical procedures, and make the patient walk in some way. Many apparently hopelessly distorted cases can be put upon their feet; even great deformity of limbs resulting from infantile paralysis, should not deter us from an attempt to straighten the limb, and give the individual locomotion. Atrophied limbs can be straightened, and can then be incorporated as a part of an apparatus; locomotion is thus to a certain degree rendered possible. Easier, quicker, and better rectification is secured by surgical than by mechanical measures in the majority of cases. Immediate rectification, if possible, should be the rule in order to save pain and time. Mechanical appliances in the shape of apparatus crutches, wheeled crutches, etc., are usually required and should be employed after straightening. Excision is capable of straightening even badly deformed limbs, and continuous improvement may be expected.

Tenotomy and myotomy do not cure the disease in either form of paralysis, but the results are most helpful in promoting the health and happiness of the individual. Wheeled crutches are very helpful in getting these helpless individuals upon their feet. These supports can be made of inexpensive material, and on a simple plan. In spastic cases relapse is much more common than in infantile paralysis, but the great benefit to the body and mind of the individuals that is secured by locomotion amply repays for the attempt at rectification.

The Operative Treatment for Spastic Paralysis.—Dr. L. A. Weigel, of Rochester, N. Y., reported a case of a very severe grade of this affection, in a girl fourteen years of age, treated by division of the shortened tissues and the subsequent application of apparatus. The result, as shown in photographs, was exceedingly good.

Injuries to the Sacro-iliac Junction.—Dr. Benjamin Lee, of Philadelphia, completed the histories of the cases reported upon at the last meeting, and added two new cases. The treatment is by an apparatus which makes strong compression of the pelvis laterally, and also practically limits forward bending. To enable a patient to pick up an object from the floor, an ingenious device, called a "teledactyl," has been devised. It consists of a spring forceps at the end of a cane, operated by a cord carried to the handle and provided with a ring for the forefinger. The lower end of the forceps is slightly bent in order to accommodate it to the horizontal plane of the floor, and the jaws are somewhat serrated.

The Diagnostic and Prognostic Value of High Temperature in Chronic Joint Disease.—Dr. R. W. Lovett, of Boston, sent a paper in which he said that high temperature is the constant accompaniment of acute hip disease and Pott's disease. The rise occurs independently of the formation of pus, and cases with unopened abscesses do not, as a rule, present a higher temperature than those where no abscesses are to be detected. The afternoon rise is from one to four degrees, and in a general way the rise is greater in the severer cases. Convalescent cases, and cases in the later stages who are doing well, are more likely to present normal temperature, and the occurrence of high temperature is to be accounted a warning of trouble.

AMERICAN PHYSIOLOGICAL SOCIETY.

Fourth Annual Meeting, held at the Arlington Hotel, Washington, D. C., Tuesday, September 22, 1891.

(Continued from p. 387.)

Third Day, Thursday, September 24th.

Some of the Influences Which Determine the Strength of Voluntary Muscular Contractions.—Dr. W. P. Lombard, of Clark University, Worcester, Mass., read a very interesting paper on the various influences which determine the strength of voluntary muscular contractions. Dr. Lombard conducted all of his experiments upon himself, and it was not until he had made a large number of experiments, so that it became a matter of routine, that he was able to forget that he was conducting them upon his own person and obtain satisfactory results. All of his experiments were made upon the second finger of his left hand and with the flexor muscles only. The first and third fingers were inserted in stiff metal tubes, which were in turn securely fastened in clamps fastened to a table. The second finger was then attached to a cord running over a pulley to which a weight was attached. At the same time his apparatus was so arranged that each contraction of the finger muscle and the power exerted were faithfully recorded on a tracing paper.

Dr. Lombard said the weight was raised with all the strength I was capable of exerting each and every time I flexed my finger, until a time was reached when I could no longer raise the weight, and this point I called the point of fatigue.

Loss of Power Due to Fatigue of the Central Nervous System.—The point where I could no longer lift the weight was due to the fatigue of some part of the central nervous system. When this point was reached I applied electricity to the muscles of the second finger, which resulted in a firm contraction, showing that the muscles were not fatigued. That it was not the will-power that was affected was conclusively proven by the fact that when I detached my finger from the weight I had no difficulty whatever in contracting the muscles. Therefore, the loss of power must lie somewhere in the nervous system between the finger muscles and the brain.

Influences of Food, Sleep, Exercise, Weather, Alcohol, and Tobacco upon the Power of Muscle Contraction. Food.—I found, after eating a slight amount of food, that it increased the power of contraction for a short period, after which the curve again descended to where it was before the repast. As to the length of time necessary for the food to show its effect, sometimes it required ten minutes, and at other times half an hour.

Sleep.—As is the case with regard to the restoration of the various functions of the body, I also found that sleep exerted a great influence in restoring the strength of the muscle contraction.

Exercise.—In regard to long-continued exercise, I found that for about one week my power steadily decreased until about the sixth day, after which there was a steady increase of power until about the twentieth day, when it had increased enormously. On the first day I

was able to raise the weight but thirty times before reaching the point of fatigue, and on the last day I was able to raise the same weight seven hundred and seventy-eight times. The absolute time employed in these experiments was about six and three-fourths hours, so that the power was increased more than twelve times.

Influence Exerted by the Weather. The Barometer.—After working for a period of several months I found that it was not the height of the barometer that exerted the greatest influence, but whether it was rising or falling, and I found that my muscular power increased with a rising barometer, but fell with a falling one. If the barometer rose during the day or fell less than on the preceding one, my strength increased. On the other hand, if it fell more than on the preceding day there was a corresponding falling off of muscle power. I also noted that my power was greater at 6 P.M. than it was at 4 P.M. This at first I could not understand, until I found that the barometer undergoes two diurnal changes. I also found that my strength also underwent like changes. Thus, I was strongest at 10 A.M., and weakest at 4 P.M., and after this hour again increasing. It was suggested to me that if such was the case, then my power should be greater at 10 P.M., and after a series of experiments I found this was an actual fact, and I did have a 10 P.M. maximum power.

Again, in another one of my experiments, after trying my power in a valley, I ascended a mountain, and after my system had time to get accustomed to the increased altitude I found my power actually stronger at 4 P.M. than it had been in the morning, and that too at a time when it would have been at its minimum in the valley. I then descended, and I found my power decreasing as I reached the lower altitude.

Temperature.—I was working in June when the extremely hot wave came on. At first I did not notice any loss of power, but on the third day of the excessive heat my muscular power fell considerably, and remained low until the temperature fell. As the temperature fell my power increased rapidly, until at the end of three days' time my power again reached its highest point.

Humidity.—When the temperature was high I found that as the percentage of humidity increased my strength fell off much more rapidly than it did during a warmer period, when the percentage of humidity was low. I also found that, even though there was a high percentage of humidity, if the temperature was not high there was but very little decrease in muscular power. So that great humidity and high temperature combined exerted a very marked effect on muscular power, whereas slight variations of humidity without a high temperature exerted but very little influence upon it.

Alcohol.—During one of my experiments I took a small glass of wine, and on looking over the record on the apparatus I found that at the time my power went up greatly. The next morning I again took some wine, and the result was the same. That night I took some whiskey and water, and the effect was most remarkable; my power increased so much that it went higher than the tracing-paper on my apparatus would record. The experiment with the whiskey was repeated a few days afterward, with precisely the same results.

Tobacco.—One evening, at a time when my power should have been rising toward its maximum, I smoked a cigar, and to my surprise I found immediately afterward my strength dropped down to a point very near its minimum. This experiment I repeated in the morning; first testing my power and then smoking a cigar, and the record showed a great falling off in strength. This decrease lasted for some time, until the effects of the tobacco had had time to wear off, after which my power again returned.

Is the Mind Similarly Affected with the Nervous Centres of the Muscles?—On this point I can say, from observations made upon myself and others, that more and better work can be accomplished by the brain in the morning up to 11 A.M. than can be effected after that hour. The period of greatest decrease of mental activity I found to be between 3 P.M. and 4 P.M., and after 4 P.M. the mind again increased in activity until after 6 P.M., and it was as active as before 11 A.M. This has a practical bearing on the fact that students rarely accomplish any work in the afternoon, and that their best work, which is accomplished between the hours of 7 P.M. and 12 P.M., is due to an increased activity of the brain, and not to the quiet that prevails during those hours.

During the discussion which followed DR. J. W. WARREN, of Boston, Mass., asked if the alcohol and tobacco effects were extended over any number of experiments.

DR. LOMBARD replied that if he smoked before each observation, for a certain number of days, the power fell throughout those days, but when he stopped smoking his power again returned.

DR. WOOD, of Philadelphia, wanted to know how the ordinary laborer, who smoked constantly, was able to accomplish any work.

DR. LOMBARD replied that when he smoked he sat in a chair, whereas the laborer was moving about. The laborer also performed his work in a very slow manner, while his contractions of muscles were done quickly. The individuality of the comparison must also be taken into account.

DR. WOOD objected to the experiment on the tobacco being made upon himself, on the ground that in his own experiments upon himself, with various poisonous drugs, he found that he was unable to overcome the power of imagination, and that he thought he felt their poisonous effects when he actually had not.

To this objection DR. LOMBARD stated that such imagination could possibly have had no effect whatever on his results, owing to the fact that he had always considered tobacco in the light of a stimulant, and was surprised to find the effect directly the reverse. In regard to the increased power caused by the effects of the alcohol, he stated that he took but very small quantities, and whether there would have been a depressing after-effect from larger quantities, he was unable to say. However, he would say that there was positively no depressing after-effect from the small quantities taken by himself, and there was a remarkable increase of power after taking it.

DR. H. P. BOWDITCH, of Boston, Mass., followed with the reading of a paper on "The Fatigue of Nerve-fibres Studied by Means of the 'Action' Current."

Diurnal Changes in Nerve-cells as the Result of the Normal Activity and Rest of the Animal.—DR. C. F. HODGE, of Worcester, Mass., read a paper on this subject. He presented a series of experiments, and in all of these he showed that there was a decided shrinkage in the nuclei of all the nerve cells examined in the evening, compared with those examined in the morning. He exhibited a number of specimens of his work, under the microscope. His experiments were not yet completed, as he had up to the present confined them to birds and bees, but it was his intention to finish his experiments on mammals.

A New Bacterial Product from Typhoid Germs.—DR. V. C. VAUGHAN, of Ann Arbor, Mich., read an abstract from a paper on a new bacterial product which he had obtained from typhoid germs, which had something of a definite chemical composition. It dissolves in water and forms an acid solution, and contains no sulphur. The question for him to decide is, whether it is a bacterial product, or whether it is not a part of the bacterial cell. This new substance is highly poisonous. When injected into animals it causes a rise of temperature and death. Ten milligrammes injected into a guinea-pig caused its death in half an hour.

The session was closed by the reading of a paper on the "Size of the Cranial Nerve in Man," by DR. H. H. DONALDSON, of Clark University, Worcester, Mass.

ASSOCIATION OF AMERICAN ANATOMISTS.

Third Annual Meeting, held in the Grand Army Building, Washington, D. C., September 23, 24, and 25, 1891.

First Day, Wednesday, September 23d.

President's Address.—The meeting was called to order by the Acting President, Dr. Frank Baker, of Washington, who opened the session by paying a glowing tribute to the memory of the late President, Professor Joseph Leidy, whose death had occurred since the last regular meeting.

The Secretary followed with the reading of a report of the Secretary and Treasurer of the Association, after which ballots were cast for the election of thirteen candidates for membership, all of whom were declared duly elected.

On motion the chair was directed to appoint a committee to nominate officers to serve for the next two years; also a new member of the Executive Committee to serve for a period of one year.

Dr. Harrison Allen, of the Committee on Anatomical Nomenclature, reported progress. Said report being accepted.

After all the regular business was finished, the Association then proceede ' with the reading of papers.

The Systematic Use of the Eye in Teaching Anatomy.—Dr. William P. Carr, of Washington, D. C., read a very interesting paper on this subject, and accompanied the reading by a demonstration of a brain model.

Some Impressions on the Teaching of Anatomy to Medical Students.—Dr. Harrison Allen, of Philadelphia, read a short but very clear paper on this subject.

The Study of Anatomy from a Physiological Standpoint.—Dr. Reyburn read a paper on this subject, at the finishing of which all three papers were discussed together by Drs. Charles Heitzman, of New York; Frederic Gerrish, of Portland, Me.; Theodore Nicholas Gill, of Washington, D. C.; Francis John Shepherd, of Montreal, Canada; and by request, Professor D. J. Cunningham, of the Dublin University.

Second Day, Thursday, September 24th.

The session was opened with a continuation of the discussion of the preceding day, on the teaching of anatomy, and was participated in by Drs. Carr, Allen, and Baker.

The Arrangement of the Supra-cerebral Veins in Man.—Dr. William Browning, of Brooklyn, N. Y., read a very interesting paper on this subject, and which bore on Hill's theory of developmental rotation of the brain. Dr. Brown illustrated his reading with the aid of models and drawings. The paper was discussed by Dr. Baker

Fissures of the Cerebrum.—Professor D. J. Cunningham, of the Dublin University, read a paper on the central, pre-central, and post-central fissures of the cerebrum. This paper elicited a somewhat lengthy discussion on the part of Drs. Gill, Allen, Carr, and Baker.

Morphological Importance of the Membranous or Other Thin Portions of the Parietes of the Encephalic Cavities.—Dr. William Browning read a short paper on this subject, which had been written by Dr. Burt G. Wilder, of Cornell University.

The Alleged Lateral Orifices, Communications of the Fourth Ventricle with the Subarachnoid Space. Are they Natural?—The paper on this subject, read by Dr. Browning, was also written by Dr. Wilder. This paper was a reply to part of Dr. F. W. Langdon's paper, "Homology of Cerebro-spinal Arachnoid with the Other Serous Membranes," which was read at the Boston meeting in 1890.

The Structure of Basic and Cement Substance.—Dr. Charles Heitzman, of New York City, read an elaborate paper on this subject, which was afterward discussed by Dr. Baker.

At this point of the meeting the rules were suspended, and balloting for several candidates for membership proceeded with, all of whom were declared duly elected. Professor D. J. Cunningham, of Dublin University, was then elected an honorary member of this Association.

Serial Fœtal Sections.—Dr. W. M. Gray, of Washington, D. C., exhibited a number of sections of the human fœtus which were mounted on frames and accompanied by photographs, and explanatory remarks upon the sections.

Dr. Allen followed with remarks upon "The Teeth of the Chiraptera."

Dr. W. H. Pancoast, of Philadelphia, by invitation of Acting-President Baker, made some very instructive remarks upon the metacarpus and its nomenclature.

The title of a paper on "Recent Fissural Diagrams," by Dr. Burt G. Wilder, was read by Dr. William Browning, and printed copies circulated among the members present.

The day's session was closed by remarks by Dr. F. H. Shepherd, of Montreal, on "Supernumerary Digits in Man and the Pig," and illustrated the same by the exhibition of specimens.

Third Day, Friday, September 25th.

Election of Officers.—The morning's session was opened by the reading of the minutes of the two preceding days. After the Secretary read a report from the Auditing Committee, the nomination of officers to serve during the next two years was proceeded with, and the following were elected to the respective chairs: *President*, Dr. Harrison Allen, of Philadelphia, Pa.; *First Vice-President*, Dr. Charles Heitzman, of New York City; *Second Vice-President*, Dr. Theodore Nicholas Gill, of Washington, D. C.; *Secretary and Treasurer*, Dr. Daniel S. Lamb, of Washington, D. C.; *Member of the Executive Committee*, Dr. E. C. Spitzka, of New York; *Delegate to the Congress*, Dr. Francis S. Shepherd, of Montreal, Canada; *Alternate*, Dr. Robert W. Shufeldt, of Washington, D. C.

The Relative Frequency of the Psoas Parvus Muscle in the Colored Race.—Dr. E. A. Balloch, of Washington, D. C., read a very interesting paper on this subject. He stated that in his dissecting-room, whenever sought for, this muscle was found on both sides in the negro subject, and the absence of it was the exception to the rule—so much so, that when it was absent on either side a note was made of it.

Dr. Balloch's experience was substantiated by that of Dr. Carr.

This paper caused quite a lengthy discussion, in which it brought out the fact that these muscles invariably existed in the ape, and that it would be very desirable to keep a record of all cases where they existed, both in white and negro subjects.

Dr. Allen stated that under the present method of conducting dissecting-rooms it would be a very difficult matter to obtain reliable statistics on this subject, and offered a resolution to the effect that this Association should have a number of circulars printed and distributed to all the anatomists of the various schools throughout the country, calling their attention to this fact, and requesting them to institute a search for these muscles in all subjects and keep an accurate record of the results obtained. This resolution was adopted.

Anomalies.—During the discussion on the paper just read, Dr. Gerrish stated that in speaking of anomalies, he wished to call attention to a very remarkable case in his own experience. The subject was the body of a married woman who, while living, gave no signs that would indicate any abnormalities. The post-mortem examination gave the following results: The foramen magnum was so small that he could only insert the point of his small finger. The right kidney was missing, and the left one was about fifty per cent. larger than a normal one should be. The bladder was an enormously large one, very thin and flabby. The uterus was bihorned. So un-

usual was it for four such striking abnormalities to exist in one subject that he called in three other physicians to examine the body with him.

Comparative Osteology of the North American Pygopodes.—Dr. R. W. Shufeldt read a paper on this subject, illustrating his remarks with anatomical specimens and upon the blackboard.

Supra-condyloid Process in Man.—A paper on this subject was read by Dr. Daniel S. Lamb, of Washington, D. C., who exhibited some specimens showing these processes very distinctly.

Platycnemic Tibias.—Dr. Frank Baker made some remarks bearing upon this subject, and exhibited some very fine specimens.

Dr. G. W. West followed by reading a very elaborate paper upon the history of anatomy as a science.

Mr. Frederick A. Lucas, of Washington, closed the reading of papers by reading one "On the Homologies of the Principal Bones," and exhibited some very fine specimens mounted in cases. He also exhibited a specimen of congenital union of the quadrate jugal to the mandible in a cockatoo, with remarks upon the same.

The session was brought to a close by the reading by the Secretary, in the absence of their writers, the following papers by title only: "The Fossa Prænasalis," by Dr. Thomas Dwight; "Notes on the Hearts of Certain Animals," by Ida Hyde; "Certain Modificatious in Plant Morphology Produced by External Conditions," by Dr. W. P. Wilson.

AMERICAN PEDIATRIC SOCIETY.

Third Annual Meeting, held at the Arlington Hotel, Washington, D. C., September 22, 23, 24, and 25, 1891.

(Continued from p. 388.)

Third Day, Thursday, September 24th.

Hip-disease in Colorado.—Dr. John M. Keating, of Philadelphia, sent a paper entitled "Tubercular Ostitis of the Hip, Originating in Colorado," which was read by Dr. W. P Watson. The case was that of a boy, aged six years, whose family history was tubercular, the father having died of phthisis not long before the birth of the boy, which occurred in Colorado.

Laryngeal Tubes for Forcible Respiration.—Dr. J. O'Dwyer, of New York, gave an exhibition of laryngeal tubes for the performance of forcible respiration. He showed the apparatus, which consisted of a curved tube with a cone-shaped extremity grooved so as to hold its place between the vocal cords, and a piece of rubber tubing attached to a bellows. The exhibitor detailed his idea as to the advantages of the method of forcible respiration. The tube could be readily introduced through the mouth and the conical end would by its grooved lines be held in position in the larynx. The bellows could be easily managed by working with one foot, and artificial respiration maintained for a long period. He advocated its use in opium, chloroform, and other forms of poisoning as superior to the means usually taken to produce artificial respiration.

Dr. W. P. Northrup, of New York, thought that the method of forcible respiration by means of this tube would prove of service in many cases.

Dr. C. P. Putnam, of Boston, said that the simplicity of the invention was in its favor.

Dr. W. D. Booker, of Baltimore, asked if the apparatus could be used in the newly-born to overcome atelectasis.

Congenital Wryneck with Facial Atrophy.—Dr. William Osler, of Baltimore, read a paper on "The Association of Congenital Wryneck with Facial Hemiatrophy." The paper included the notes of a case that had been observed by the author, and the literature of the subject. He stated that all the cases recorded had shown the condition to exist on the right side with apparent hypertrophy of left sterno-cleido-mastoid muscle. In none of the cases had there been progressive wasting. A positive explanation of the pathological condition had not been made.

The Application of Gavage in the Treatment of Uncontrollable Vomiting in Infants.—Dr. Charles G. Kerley, of New York (by invitation), read a paper with the above title. In advocating this method the author of the paper advised that the child should not be held erect as in stomach washing, but be kept in a semi-recumbent position. The operation should be done quickly and predigested food introduced. He had found that Paine's adult nasal feeding-tube, No. 13, was preferable to the ordinary soft catheter used in stomach washing. He believed that he had saved life by this method.

Dr. L. E. Holt, of New York, added his testimony to the efficacy of gavage in the vomiting of infants.

Dr. W. D. Booker said that the results reported showed the advantages of gavage as detailed in the histories of the cases detailed.

Dr. J. O'Dwyer gave as his opinion, based on cases of forced feeding in children after intubation, that the food had always been rejected. The patients were most of them over eighteen months, and not so young as those treated by the author of the paper.

Dr. C. P. Putnam thought the method of great interest and value.

Dr. H. Koplik, of New York, had listened with interest to the histories of the cases. He desired to know why when infants had vomited that the stomach had not been allowed to rest. He wished to know what advantage gavage had when food had been rejected?

Dr. A. Seibert, of New York, believed that in stomach catarrh in infants there is always a similar condition of the pharynx and mouth. When the tube was introduced into the stomach the food reaches the stomach without being contaminated by the condition of the upper passages; thus the food would be received without the admixture of material, which would be apt to interfere with its digestion or produce further disease.

Dr. Kerley concluded by expressing his belief that he had saved by gavage the lives of infants who had failed under all other plans of treatment.

Scurvy in Children.—Dr. W. P. Northrup, of New York, read a paper and presented microscopic slides with drawings of scorbutus in children. Nine typical cases were collected from New York, and the Board of Health had the records of sixteen more fatal cases under five years of age which had occurred in the past twenty years. England seemed to have furnished most of the literature on the subject. The paper showed that the most diagnostic symptoms and signs were pain and swelling over the femora, with a sponginess of the gums. On a dietary of fresh vegetables, fruit, and milk the patients had recovered. Orange-juice was craved by all of the children.

Dr. Holt had reported a case to the author which at the time he had believed to be scurvy. Death and an autopsy since had confirmed the views he had had of the case. His history agreed with the picture given in the paper.

Dr. Booker gave the history of a patient which corresponded in every particular with the typical case narrated by the writer of the paper.

Dr. J. H. Fruitnight reported a case of scorbutus in a girl of five years. He regarded the disease as rare.

Dr. Putnam had observed three cases of scorbutus in children, of which one had died. Proprietary foods and condensed milk had had something to do in producing the disease.

Dr. A. Jacobi, of New York, had missed in the paper the definition of what had been called scurvy. He desired to know whether bleeding from the gums should be considered a characteristic feature. The association of scurvy with some of the hemorrhagic diseases he believed o be a close one. In scurvy the hemorrhage does not t

occur into the joints, but is limited by the epiphyseal line. He would not place subperiosteal hemorrhage as the most diagnostic symptom, because it could be observed in other diseases. The speaker would like to know the conditions of the blood-vessels, and thought the subject offered a great field for investigation.

Dr. Northrup closed the discussion by a statement that subperiosteal hemorrhage, with some swelling of the gums, with or without hemorrhage, should be regarded as scorbutic. Prompt recovery should also be looked for under appropriate treatment. He aimed to stop where his facts stopped. No one could to-day explain blood dyscrasias.

Dr. S. S. Adams, of Washington, read by title his paper on a "Study of Fifty Cases of Chorea." He then exhibited a patient, a boy, aged nine years, showing pseudo-hypertrophic paralysis.

Nephritis in Children.—Dr. L. Emmett Holt, of New York, reported two cases of acute primary nephritis in infants. The author gave the details of the clinical histories. The first patient was six months old and died after an acute illness of seventeen days, the predominating symptoms being continuous temperature of a high remittent type, dulness, apathy, and anæmia. Mild gastro intestinal symptoms were present. There was no dropsy or suppression of urine. The second case was thirteen months old and the symptoms very similar, and lasting twenty-two days; the temperature ranged from 101° to 105° F. The autopsies in both cases showed a very extensive and well-marked acute diffuse nephritis. The first child had never had any infectious disease, the mother stated, and there were no throat symptoms and no signs of desquamation. The last child had been under observation in an institution for eight months prior to the fatal illness, and had had no sickness during that time.

Chronic Nephritis in Children and Young Adults.—Dr. Henry Jackson, of Boston, sent a paper with this title, which was read by Dr Putnam. The article was based on reports of cases observed in private and hospital practice. The author thought that the text-books had perhaps neglected the disease, and that it might be of much more frequent occurrence than we had been led to suppose. The clinical observations of the patients seen by the author were carefully made and recorded. He gave no therapeutics for the disease, as the paper was a narration of symptomatology.

Scarlatinal Nephritis in Children.—Dr. J. L. Smith, of New York, read a paper on this subject. While he regarded this form of kidney disease as associated with a microbic origin, he did not think that it should be lost sight of that exposure to cold would often induce an attack of nephritis. The paper was an exhaustive one and dealt with the subject as a continuation of the paper read by the author at the first session.

Discussion on Nephritis.—Dr. A. Seibert, of New York, had put to himself the question, Where had the infection come in the cases of acute nephritis reported? He desired to call attention to the mild acute tonsillar attacks in infants which might originate nephritis. Varicella might also be the starting-point of kidney disease.

Dr. Forchheimer, of Cincinnati, thought that the predisposing influence in scarlatinal nephritis was the virus, and not "catching cold." He had made comparison of the cases that he had kept in bed and those who had not been so protected, and he did not believe that the latter class had had more severe nephritis.

Dr. Putnam had had experience similar to that of the previous speaker, and thought that exposure had had little influence.

Dr. Koplik, of New York, was glad to hear that the concensus of opinion was in favor of the view of the infection of the kidneys in the cases reported.

Dr. Fruitnight thought that cold had some effect in the disease.

Dr. Northrup had had a case of acute nephritis similar to those reported, with high temperature and the other severe symptoms.

Dr. Smith thought that a great many cases could be traced to scarlatina of a mild type.

Dr. Jacobi had seen a great many cases of primary nephritis. He would call attention to the need of more frequent examinations of the urine of children. The speaker expressed his opinion decidedly as to causation of kidney disease by exposure to cold. Intestinal disorders might be the signs of kidney disease. An examination of the urine would be made in such cases if observed in the adult and it should not be neglected in a child.

The President expressed the opinion that exposure to cold did produce kidney disease in scarlatina.

Dr. Seibert believed in fresh air and gave the particulars of cases of scarlatina which he had treated by keeping the patients in rooms opened to the air without bringing on kidney lesions.

Dr. W. L. Carr, of New York, inquired why it was that the cases of so-called mild scarlet fever were the ones that applied at the out-door departments of hospitals for nephritis. He believed it to be because the exposure in such patients had some effect in causing kidney complications. Hospital statistics had shown that the lowest percentage of nephritis occurred in patients kept quiet in bed.

Dr. Charles W. Earle, of Chicago, sent a paper on "Manifestations of La Grippe in Children," which was read by Dr. Seibert.

Fourth Day, Friday, September 25th.

Stomatitis Aphthosa.—Dr. F. Forchheimer, of Cincinnati, read a paper entitled "The Etiology of Stomatitis Aphthosa," of which he gave the following summary: 1. Stomatitis aphthosa is a disease produced by some form of deleterious material in the circulation. 2. The material may have its origin in various processes, bacterial or otherwise. 3. This material may, therefore, be of various kinds. 4. This material acts upon a nerve or nerves, upon a nerve-centre or nerve-centres; 5, Producing an herpetic eruption, which is the aphthous process.

Dr. H. Koplik, of New York, thought that the paper brought the subject to the front of the literature. He narrated particulars of Epstein's views of traumatic aphthæ.

Dr. C. P. Putnam, of Boston, said that if herpes zoster and herpes labialis could be caused by irritation of the nerves, he wondered why aphthæ could not be due to irritation of the mucous membrane.

The President did not make use of the word aphtha, as the definition was uncertain and was apt to be misunderstood. He would like a qualifying adjective to the word stomatitis instead of the use of aphtha.

Dr. S. S. Adams, of Washington, thought that the disease must be regarded as a distinct form. He had noticed a contagious element.

Dr. Putnam would like to have a committee appointed to consider the nomenclature of the diseases of the mouth in infants and children.

Dr. Forchheimer, in closing, replied to inquiries that reflex conditions did not play much part in the causation of herpes. There was atrophic disturbance of the ganglia. He further stated that he had, in his study of the diseases of the mouth, designated the conditions as stomatitis, and used the aphthous qualification as an objective and not as a noun. Diphtheritic stomatitis was very rare, but the presence of stomatitis aphthosa was common in diphtheria.

The President and Dr. F. Forchheimer were appointed a committee to consider the nomenclature of the diseases of the mouth in children.

Perityphlitis in the Young.—Dr. J. H. Fruitnight, of New York, presented a paper with the above title. The author formulated the following conclusions for treatment: 1. In cases of a chronic or subacute perityphlitis, without a tumor or with a small tumor, the expectant plan of treatment should be followed. 2. In

cases of chronic or subacute perityphlitis with a growing tumor, with or without evidence of suppuration, extra-peritoneal incision or aspiration should be done. 3. In cases of acute perityphlitis with threatening symptoms, with tumor, and hyperacute cases without appreciable tumor, exploratory incision (extra- or intra-peritoneal) should be made.

Dr. Putnam said that pain was not always localized. Usually he had found general pain. He should use milk in some form for nourishment, because he thought it too valuable to be discarded.

Officers for the Ensuing Year.—*President*, Dr. William Osler, of Baltimore; *Vice-President*, Dr. J. M. Keating, of Philadelphia; *Secretary*, Dr. S. S Adams, of Washington; *Treasurer*, Dr. C. W. Townsend, of Boston; *Recorder*, Dr. W. P. Watson, of Jersey City.

Dr. W. D. Booker, of Baltimore, was made a member of the Council.

The Society then adjourned, to meet in Boston during May, 1892.

Progress of Medical Science.

Subcutaneous Emphysema following Broncho-pneumonia.—Dr. Damsch, of Göttingen, points out that the occurrence of subcutaneous emphysema in association with disease of internal organs is extremely rare. It is generally produced during some act of respiratory effort, such as straining, prolonged crying, violent vomiting, etc., but is commonly found to be limited within the alveolar or subpleural tissue of the lung itself—the so-called interlobular emphysema. This condition is not always productive of diagnostic signs, unless it spreads to the mediastinal tissues. Children are on all hands admitted to be more liable to rupture of the pulmonary alveoli than adults, but almost all writers agree that simple whooping-cough, unless accompanied by tuberculous or inflammatory disease, is hardly ever productive of subcutaneous emphysema. The latter has been produced by phthisis, especially where tuberculous ulcers are present in trachea or bronchi, and by other forms of disease tending to weaken the bronchial walls. The air, as a rule, passes from the mediastinum to the surface along the course of the great vessels. A case is recorded in which a gradually progressive condition of subcutaneous emphysema affecting the left half of the head, face, and body, showed itself in an infant, aged fifteen months, in the course of broncho-pneumonia of both bases. The emphysema attained a degree described as monstrous, but the child did not appear to suffer from it, becoming quietly somnolent until its death. On examination, it was found that extensive interstitial emphysema was present over the upper lobes of both lungs, forming several rows of tiny subpleural bubbles, some of them as large as a bean. The rest of the lungs, except where consolidated by the broncho pneumonia, were somewhat dry and anæmic. The tissues of the mediastinum were emphysematous, but the pericardium was free, and the air was found to have reached the surface by the usual route.—*Deutsche Medicinishe Wochenschrift.*

Gastrostomy in Cancer of the Œsophagus.—Drs. Terrier and Louis, of the Hôpital Bichat, Paris, advocate this plan of treatment, the frequently fatal results of which, it is held, are due more to the enfeebled condition of the patient than to any risks attending the operation itself. The authors consider how certain inconvenient results which have been observed in cases of recovery may be prevented by improved methods of operating, and sum up their views in the following conclusions: 1. Gastrostomy in cases of cancer of the œsophagus is decidedly a justifiable palliative operation, and ought to be proposed to the patient. 2. Its performance is very simple, and the immediate results are not attended with much gravity. 3. The ulterior evils due to the presence of a gastro-cutaneous fistula may be avoided by opening the stomach as near as possible to the superior curvature, by making only a small orifice, and by dispensing with the subsequent use of occluding agents. 4. Then simple dressings only will be needed, and these should consist of inert powders, or of such (carbonate of magnesia, for instance) as are capable of neutralizing any drops of gastric fluid that might be discharged during any forcible effort made by the patient. 5. The results of gastrostomy with regard to the survival of the patient are influenced by the duration of the disease and the extent to which the stomach is involved. Certainly in France intervention, as a rule, is too late, and the chances of survival are consequently much diminished.—*Revue de Chirurgie.*

Operation for Tumor Pressing on the Cauda Equina.—Dr. Leopold Laquer, of Frankfort, gives an account of a case in which, from the symptoms and history, he was able to diagnose some growth in the sacral canal exerting pressure on the roots of the cauda equina (*The Lancet*). The patient was a young man, aged nineteen, with an excellent family history, and in whom any specific affection could be excluded. He began in September, 1888, to suffer from severe pain in the middle of the sacrum. This spot was also very sensitive to pressure. The pain, although for the most part confined to the spot mentioned, not infrequently spread to the knees on each side, and no impression could be made upon it with all the anti-rheumatic and other drugs which were tried. It was much worse at night than at other times. Counter-irritation and galvanism effected temporary improvement. The pain was always worse when sitting or lying down, and he was able to walk for an hour or two without much trouble. This was when he first came under observation. At this time all the movements of the different joints could be carried out, the knee-jerks were present, and there was no trouble with the sphincters. There was no muscular atrophy, no disturbance of sensibility, and all the muscles reacted well to both currents. After the temporary improvement following counter-irritation and galvanism, his condition became progressively worse; the pains were more severe, there was some wasting of the quadriceps, the knee-jerk could only be obtained with difficulty on one side and was absent on the other, there was pain upon defecation and micturition, and there was difficulty in emptying the bladder. Power of progression also was more difficult, and the patient was much bent when he walked. There was no impairment of sensibility to be discovered. The electrical reactions were unchanged. A diagnosis was made of a new-growth in the sacral canal, compressing the cauda equina. The operation of opening the canal was effected by Dr. Louis Rehn, and a cavernous lymphangioma was found which was extra-dural, but had pressed the dura and the cauda equina from before backward. The patient made an excellent recovery, losing his pain and regaining all his former power.

Etherization in Laryngeal Croup.—Dr. Betz reports the case of a child, aged eighteen months, that presented the typical symptoms of laryngeal croup. The case appeared so hopeless that tracheotomy was, although proposed, rejected. Dr. Betz then proposed "etherization." Three drops of a mixture of ether sulph. 3 parts, acetic ether 1 part, menthol 0.1 part, were ordered to be inhaled every quarter of an hour, just as chloroform is inhaled. It was hoped that the cold from the evaporating mixture would contract the surface blood-vessels of the larynx, and thus reduce the œdema present. The child was seen again in two hours, and the condition had somewhat improved. The etherization to be continued, 3 to 4 drops every half-hour. After six hours the condition was unmistakably better, so much so, in fact, that the etherization could be dispensed with. A piece of intestine filled with ice was placed around the child's neck. After this progress was so rapid that in twenty-four hours the child was out of danger.—*Memorabilien.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, October 3, 1891.

REST AND SURGICAL THERAPEUTICS.

IN an address on surgery, delivered before the British Medical Association, by Dr. John Chiene, a text from John Hilton—"Rest as a Therapeutic Agent in the Treatment of Surgical Ailments"—is taken, and many practical suggestions are drawn from it. Dr. John Hilton lived long, practised and thought much, but he wrote little. His book, "Rest and Pain," was in a measure forced from him by the demands of a lectureship, but it gave him deserved fame, and the principles he inculcated have been fruitful of good. Dr. Chiene has taken Hilton as a guide in many departments of his surgical practice, and we give here some of the fruits of his experience in applying the principle of rest. He says:

"Use leaden splints to steady limbs after amputation and excision. Shape the splint so that it can be unfolded without moving the limb. Anchor the arm by the side with a leaden splint after excision of the mamma. Apply your pressure firmly, but always leave a distal portion of the limb exposed, so that, if it swells, then the pressure is overdone and the bandage must be loosened. We know pressure is properly applied to any part if it fulfils two conditions—painlessness and non-interference with the blood-current through the part.

"Horse-hair stitches are valuable, combining rigidity and elasticity—rigidity acting as a splint steadying the edges, elasticity enabling them when cut to be removed without pain. After cutting a stitch, lay hold of the knot and pull toward the side on which the loop has been cut; in this way all strain on the edges of the wound is avoided.

"A plaster applied over a boil in its early stages acts as a splint, steadies the part, and relieves pain. The boil is frequently aborted by this simple means."

"In intracranial hemorrhage, intra- and extradural, we now feel justified in cutting down and arresting the hemorrhage by ligature, or by the hot douche, and from one case in which I operated on a person, comatose, with Cheyne-Stokes respiration, and a pulse of forty to the minute and on the point of death, I feel justified in recommending that, in apoplexy, an opening into the cranial and dural box is a justifiable surgical procedure, giving rest by relieving tension."

"In the case of nerve-stretching in sciatica, the cases which are benefited are, in my opinion, those which may be called trade sciaticas, due to some special position adopted in the special trade pressing on and irritating the sciatic nerve. You freely stretch the nerve, but do not interfere in any way with the sensory and motor functions, and the pain is relieved by breaking down the fibrous adhesions in the nerve sheath and among the nerve fibrils. May I say in passing that the operation is sometimes a source of psychical unrest to the operating surgeon if he does not easily find the nerve; this unrest is avoided if, in operating, the patient lying on his face, the surgeon will stand on the opposite side to the limb to be operated upon. If he then makes an incision over the nerve at the lower border of the gluteus maximus large enough to enable him to introduce his forefinger, which, using as a hook, he draws toward the middle line of the patient, he will at once find the nerve lying external to the muscles arising from the tuber ischii.

"There is no organ," Dr. Chiene continues, "in which the value of rest is better illustrated than in the bladder. In disease its systole and diastole can be checked in different ways, and the cystitis caused by the unrest, as evidenced by frequency of micturition, is relieved. This can be done by fixing a gum-elastic catheter in the bladder, taking care that the eye of the instrument is just within the cavity, and attaching to the catheter an india-rubber tube which passes into a vessel at the side of the bed. In 1876 I showed that if the tube passes under water, and if the instrument and tube are full of fluid, there will be, by the siphon action of the arrangement, if the water in the vessel is at a lower level than the bladder, a head of water, which, by its suction, will remove the water from the bladder as it passes from the ureters. The amount of suction will depend on the difference of level, and I have found by experience that a foot of fall is generally sufficient to keep the bladder empty. If the fall is greater, then the mucous membrane is apt to be sucked into the eye of the instrument, and a block takes place, the bladder filling with urine. When this happens pain will at once be felt by the patient; in fact his sensations are the best guide to the height at which the vessel at the side of the bed should be placed. By this simple means we can give the bladder rest."

"In the ligature of internal piles the division of the mucous membrane at the anus with scissors before transfixion and ligature, and tying the ligature tightly so as completely to strangulate the pile, are both means which diminish pain after the operation. The pile mass dies without any inflammation, it dies of dry, painless gangrene. If this had been more frequently attended to we should have heard less of other methods of treating internal piles. While I say this, I desire most emphatically to express my complete accordance with Whitehead's view, that in cases in which the whole circumference of the gut is affected excision is the most thorough and satisfactory method of treatment."

"In epistaxis prevent the air passing through the nasal cavity by tightly grasping the nose, and the epistaxis will frequently cease, the part being kept at rest."

"In the diagnosis of injuries in the region of the hip, the use of Nélaton's line has been given up in my practice, because in order to reach the ischial tuberosity necessary for estimating the line the patient has to be moved. Its place is taken by noting the want of parallelism between two tapes, one passing through the anterior supe-

rior spinous processes, and the other through the tips of the great trochanters of the femur."

While some of the foregoing hints may be regarded rather as surgical "wrinkles" from the practice of Dr. Chiene, they are all, he asserts, suggested by the teachings of Dr. Hilton, and they all more or less give force to the value of the rest element in the treatment of surgical ailments.

THE TREATMENT OF ERYSIPELAS.

Erysipelas is one of those diseases for which so many specifics have been recommended that one is inclined to doubt whether medication is of any value whatever. Its therapeutics, like that of many other infectious disorders, has followed certain fashions. It is not so long ago that the use of tincture of iron in large doses was most extensively employed, and was considered the correct and canonical, if not the only, thing indicated. Yet, in a recent elaborate review of this subject in the *American Journal of the Medical Sciences*, by Dr. Charles W. Allen, the iron treatment seems to be placed much in the background.

Dr. Allen's article is based on a study of 466 cases treated in hospital and private practice.

Some interesting clinical facts are first brought out. It is shown that the disease is much more prevalent in the cold and damp months, from January to June, 243 out of 300 cases occurring at that time.

About two-thirds of the cases were of facial erysipelas.

The mortality of the hospital cases was five per cent. of the total cases, and 3.7 per cent. of the facial cases. The mortality was chiefly among the young.

After reporting a number of illustrative cases, in which various forms of treatment were employed, and after a *résumé* of the various therapeutical recommendations of other authors, the writer states that the plan of treatment which offers the best results is about as follows:

"First, internally, such symptomatic treatment as the nature of the case seems to require. Antipyretics only in case of high or persistent fever (over 103½° to 104° F.). Then antipyrine in dose of at least fifteen to twenty grains, for an adult, guarded by alcohol. Cooling drinks. Calomel or saline aperients in full dose, if there is constipation. If much weakness, alcoholic drinks given freely, especially at critical periods, and iron, or iron and quinine; digitalis if much fever and prostration; bromides for delirium; antipyrine or phenacetin for headache, with cold applications to head, and as concentrated and nutritious a diet as possible.

"Second, locally, I would paint the patch and surrounding margin of healthy skin thickly with ichthyol in collodion, one to two drachms to the ounce. If the scalp is the region affected, a watery solution or ointment of ichthyol can be employed. To arrest the spread I should in every case make an attempt, either with the band of adhesive plaster or by scarification, or both, the latter to follow the former, in case the disease spreads beyond the adhesive strips. In erysipelas of the face which had not yet reached the forehead, or at least its upper part, I would apply a band tightly about the forehead and just above the ears, cutting the hair in a strip around, if necessary to secure firm pressure. The chances of arresting the process here should be at least equal to those of checking the spread upon an extremity, for we have a hard bony base over which to make our compression. If the boundary is passed, then I should at once have the scalp shaved and apply another band higher up. The hair should be cut in any case in which the scalp is invaded or threatened. Then the same application of ichthyol in collodion can be made, as to the face or other part. If there be much tension, swelling, heat, and discomfort (which is not apt to be the case under collodion), any oily substance can be applied over it."

Dr. Allen dwells on the importance of treating purulent foci, if such exist. He regards facial erysipelas as of traumatic origin and essentially identical with the secondary forms. He adds that, as a prophylactic measure in those predisposed to repeated attacks, great care should be taken to discover and cure affections of mucous membranes, carious teeth, ulcerations, or other disease processes or conditions which are mentioned as possible means of maintaining the tendency. Recurrences after apparent cure must be kept in mind, and treatment continued sufficiently long to prevent them.

DRY ADULTERATION.

At the recent meeting of the New York State Pharmaceutical Association, the committee on adulteration, consisting of Dr. R. G. Eccles, W. G. Tucker, and J. C. Hubbell, made a report of examinations which had been made by its members, of several drugs obtained at retail from pharmacists in various cities of this State. This report, which we find in the *Druggists' Circular* for August, 1891, is too long to be transferred entire to our columns, but it is deserving of more than passing mention, for it reveals a state of things that it is far from pleasant to contemplate. The first drug reported upon is spirit of nitre. This is notoriously unstable in its composition, and we should not expect to find every sample up to the standard. It is, furthermore, a comparatively unimportant drug, and variations in its strength would be likely to excite less apprehension than they would, were the preparation a very active one. Yet it must have caused some astonishment, even to the members of the committee, who are presumably more cognizant of the deceptions practised by pharmacists of the baser sort than are physicians, to find that the strength of the various samples varied from double that of the standard down to practically zero. Between the two extremes there was a difference of 134 times. In other words, a teaspoonful of the strongest contained the strength of more than a pint of the weakest of those containing an appreciable amount of nitrite of ethyl. Some samples did not contain even an appreciable amount, and of the whole sixty-eight samples, forty-seven were so far below pharmacopœial demands that they merited unqualified condemnation.

Of dilute acetic acid seventy-six samples were obtained in various towns between Poughkeepsie and Saratoga. Of these eleven were found to be too strong, thirty-four much too weak, and only nineteen near enough the pharmacopœial standard to be called good, and fourteen fair. The strength should have been 6.12 per cent., but the various samples showed from 0.8 to 29.8 per cent. Of forty-six specimens of Hoffman's anodyne, only five were

good. Other samples of different dilute acids showed variations in strength similar to those found in the case of dilute acetic acid. In twenty eight samples of dilute hydrochloric acid the weakest contained only three per cent., while the strongest had no less than 31.4 per cent. Most of the specimens of dilute sulphuric acid were, however, found to be fair.

Thirty prescriptions were written for stronger ether, and for one was sent a mixture of chloroform and alcohol! The druggist that would make such a substitution as that ought to be published to the world, if not criminally prosecuted. Of the remaining twenty-nine samples, no less than twelve were inferior. Of fifteen samples of potassium iodide only three were good, and of thirteen samples of magnesia only one was of good quality.

The committee also examined a number of pills of various sorts obtained from the manufacturers, testing them as to their contents and solubility. They varied considerably in both respects, yet not sufficiently, perhaps, to interfere seriously with their therapeutic action. The widest differences were found in the compound cathartic pills of various makes, three out of the five samples tested being made of the cheaper grades of aloes and jalap, the extract of jalap being generally substituted for the abstract. All were labeled U. S. P., although their makers must have known of their failure to conform to that standard.

Is it any wonder that there is so much therapeutic scepticism among physicians of the present day? It is a suggestive fact that the firmest believers in the efficacy of drugs have always been found among the practical and hard-headed country practitioners, who put up their own prescriptions, and usually prepare their own tinctures from the crude drug. They know what they are doing, and have confidence in their own weapons.

MEDICAL FELLOWSHIPS.

The announcement of the College of Physicians and Surgeons for the coming year contains the information that the trustees of Columbia have established three fellowships, the provision for which is made annually by the Alumni Association of the college. The fellowships are to be open to graduates who have shown special aptitude for scientific research in anatomy, pathology, and physiology. They are to be held for two years and have an annual value of five hundred dollars each.

No more welcome announcement has been made for many a day than is contained in the foregoing paragraph. The time has come even here, in the United States, when the teaching of medicine ought to be entrusted to those who have made some special preparation for teaching over and above the mere college curriculum and a certain number of years of practice. All our larger academic institutions are surrounding themselves with a body of graduate students who, free from the petty tyranny of examinations, are pursuing knowledge for its own sake and for the power and influence it may give, and are not merely after a diploma. These men must, and it is proper that they should, present from time to time an original thesis, as a guaranty of their fidelity and as evidence of results accomplished. From their ranks the teaching force of our institutions is to be recruited. Their presence conduces to the establishment of a studious atmosphere about the places of their work.

It is still somewhat of a novelty, however, to have such fellowships in our medical colleges, but it is most emphatically a step in the right direction. Here, as elsewhere, teaching is becoming more and more specialized, and requiring special preparation for its proper performance. No man whose time is taken up by the daily duties of a general practice, and who has no hours regularly set apart to the work of preparation, can ever teach satisfactorily any scientific branch of medicine. He may be a fair clinical lecturer, but even then he must keep abreast of current knowledge. Fellowships will lead to the development of the right sort of men for our laboratories and dissecting-rooms.

We have already called attention to the fact that the days of the old-fashioned didactic lecture are numbered. One of our institutions has already introduced a corps of teachers, that is, conductors of recitations, and further expansion along this line will certainly come. Demonstrations in various departments must always survive as well as certain didactic forms of imparting knowledge, but the old-time medical student whose years in college represented only two or three hundred lectures, and a few scores of well-filled note-books, will soon be a thing of the past.

News of the Week.

The King of Siam's Physician.—Dr. W. R. Lee, who has been made the royal doctor to the King of Siam, is but twenty-eight years of age, and at the age of twenty-four he was driving an express wagon in Springfield, O., for a living. Dr. Lee was graduated from the medical school of the University of New York, and was originally sent out to Petcheburee, in Siam, by the Presbyterian Board of Foreign Missions.

What Elixir the Best?—A correspondent sends the subjoined clipping with the facetious suggestion that it might make a good introduction to a flamboyant advertisement: "Napoleon's disaster at the battle of Leipzig is popularly set down to his having eaten a bun in a hurry, and so brought on dyspepsia; but it would be a very curious page of history if we could learn how many wars, how much bloodshed, and how much cruelty have had their origin in imperfect action of the bowels. Washington Irving, in his "Lives of the Caliphs," tells of a certain emir, named Al Hejagi, who suffered for many years from dyspepsia and abdominal pains, and this wretched man distinguished himself, perhaps above all other rulers who ever lived, in the enormous number of people whom he sentenced to imprisonment and death. He is said to have caused the death of no less than 120,000 persons, besides those who fell in battle, and to have left 50,000 in prison when he died himself. How much of all this misery might have been averted by the judicious use of mild aperients, it is as impossible for anyone now to tell, as it is to estimate the debt of gratitude which Europe owes to the physician of Louis XIV. for the care he took of the digestive organs of that august monarch."

Dr. J. W. S. Gouley will begin a course of lectures on "Diseases of the Urinary Apparatus," at the Mott Memorial Hall, 64 Madison Avenue, on October 6th, and continue every Tuesday at 8.30 P.M., thereafter. These lectures, supplemented by clinics, in the amphitheatre of Bellevue Hospital, every Saturday at 3 P.M., will be free to the profession and students of medicine. Opening clinic October 3d.

Dr. John M. Keating, of Philadelphia, has resigned his position as director of the Penn Mutual Life Association, and has removed to Colorado Springs.

In the Matter of the Admission of Private or Pay Patients to the New York State Hospitals for the Insane.—A special session of the State Commission in Lunacy was held at the Capitol, in the city of Albany, on the ninth day of September, 1891. Present: Carlos F. MacDonald, M.D., *President;* Goodwin Brown, Henry A. Reeves, *Commissioners.* The laws of the State having declared that the State hospitals were erected and are to be so maintained and governed that the public insane patients, for which class the hospitals were established, shall have the preference—the statute expressly providing as follows: "Whenever there are vacancies in the asylum the managers may authorize the superintendent to admit, under special agreements, such recent cases as may seek admission under peculiarly afflictive circumstances, or which, in his opinion, promise speedy recovery;"—and the Commission being required, by chapter 126, of the laws of 1890, "to forthwith cause the removal . . . from the counties of . . . as many of the pauper and indigent insane as can be accommodated;" and the Commission having, in conference, requested the opinion of the managers and superintendents of said hospitals, touching the admission of private or pay patients, which, after due deliberation, was given in a resolution adopted by the affirmative vote of six of the eight hospitals—one being unrepresented and one not voting—as follows:

"*Resolved*, That it is the sense of this meeting that the State hospitals should be permitted to receive private patients from any part of the State without restriction, the rate not to exceed ten dollars per week;" and in order that the rights of the insane poor, and of such as can pay small sums only, may be fully protected by reserving to their use and benefit as much room space as may properly be required; and in order to guard against the restriction of such space by its undue allowance to private or pay patients who may desire it as an equivalent for a large weekly or monthly compensation; it is hereby

Ordered: 1. That on and after October 1, 1891, no private or pay patient at any State hospital be permitted to occupy more than one room for his or her personal use or behoof, or to command the exclusive services of an attendant; and, thereafter, there shall be no distinction permitted between public and private or pay patients as to the care and accommodation furnished them. 2. That whenever the managers or trustees shall determine that vacancies exist, private or pay patients may be admitted by them without further restriction, at a rate of compensation not to exceed ten dollars per week, preference to be given in all cases to patients of small or moderate means. 3. That this order, unless specially so directed, shall not be held to require the removal of the private or pay patients in custody October 1, 1891. 4. That this order shall take effect October 1, 1891, and on said date the order relating to private or pay patients entered September 2, 1890, shall cease and be of no effect. By the Commission. T. E. McGarr, *Secretary.*

Union Meeting of the District Medical Societies of Northern Ohio.—It has been decided by the Joint Committee appointed by the following societies, to hold a union meeting of the North Western, the North Eastern, and the North Central Ohio Medical Societies, at Mansfield, O., on Thursday, Friday, and Saturday, November 5th, 6th, and 7th.

The Third Annual Meeting of the Tri-State Medical Association of Georgia, Alabama, and Tennessee, will be held in Chattanooga, Tenn., Tuesday, Wednesday, and Thursday, October 27th, 28th, and 29th, at Turner Hall.

The Seventeenth Annual Session of the Mississippi Valley Medical Association, will be held in St. Louis, October 14th, 15th, and 16th.

A Benefactor to the Medical Profession. The recent death of Colonel Frederick A. Conkling, of this city, calls to mind some past history in reference to legalized dissection in this city. The medical profession here and elsewhere are more indebted to the Hon. Mr. Conkling for the passage of the dissection law than to any other legislator. It was by his efforts, while a member of the Assembly, in 1852, that the law of 1854, legalizing the study of human anatomy, became an accomplished fact. It was a hard fight against popular prejudice by Colonel Conkling, but his scholarly and consistent advocacy of the bill won the battle.

The Practitioners' Club of Chicago is a new medical society, which held its first banquet at the Palmer House August 31, 1891; fifty of the representative medical gentlemen of the city were in attendance.

The features of its organization are, viz.: 1. To afford the opportunity for occasional social communion in the profession. 2. To meet in a happy and informal manner those laboring in the same pathway of duty as ourselves, whether they are almost at our elbows, from the wide limits of this great municipality, or, perchance, strangers within our gates. 3. To discuss lightly—extemporaneously, so far as possible—the more timely and pertinent questions of our science. 4. To furnish a visiting brother a greater hospitality—in this direction—than would be within our power, were it not for the existence of, and our personal interest in, this medium. Dr. George Henry Cleveland is Secretary.

ficulty and an inability to do the usual amount of mental work. This patient was first seen by me in August, 1890. The present attack had commenced in December and had been caused by great grief at the death of an intimate friend. There had been marked hallucinations and delusions for several months after the onset, and even when I first saw her there was a marked mental dulness with slight hallucinations. The insomnia had been obstinate and persistent from the start, and suicidal attempts had been frequent. In the previous attack there had been well-marked post-cervical aching, but there has been none in this. This patient recovered perfectly in the course of eight weeks, with the exception of her insomnia, which is apt to recur at present from time to time.

CASE III.—Female, aged forty two. Has had very

[1] The Journal of Nervous and Mental Diseases, January, 1890.

and then excised five centimetres of the tuberculous mass. The patient was, on his recovery, exhibited before the Surgical Society.

The Society for the Abolition of the Title of Doctor receives help and encouragement in the following annotation from the *Medical Press and Circular*: "The titular appellation which medical practitioners rejoice in is a relic of antiquity akin to that of the legal wig, and it is curious in that it has survived the levelling tendencies of the present generation. A correspondent raises the question as to whether the practice is an unmixed advantage. It serves to distinguish the doctor from his fellow-men, and although from an advertisement point of view this may not be altogether a drawback, it certainly entails inconveniences of its own. It never occurs to an outsider to start a conversation with a doctor on any but a medical topic, and it is quite open to discussion, a contemporary suggests, whether, if medical men did not differentiate themselves so much, and were content to be like other educated members of the community in title, manners, and personal appearance, it would not be better for themselves both in public and private life."

Too Bad for the Doctor.—The cities of the Northwest offer very poor openings for physicians. The death-rate is probably the lowest of any great cities in the world, and there is a distressing absence of zymotic affections; while even the great resource, tuberculosis, is comparatively rare.

A Novel Cure for Nervous Diseases is being practised in Worishofen, Bavaria. The treatment is the outcome of the study of an old priest, and consists chiefly in spraying water over the body in various places, dressing at once without drying, and brisk walking immediately afterward. The diet is carefully attended to, and thousands have been cured of nervous troubles which had defied all previous physicians.

The Electric Fan has been suggested as a useful antipyretic in fevers.

The First Colored Female Doctor.—Novelties in the way of doctors *quoad* race, sex, sect, condition, etc., have become somewhat rare of late. We have recorded the evolution of the first Chinese doctor, the first female homœopathic doctor, the first lady medical Brahmin, etc. Despatches now furnish us with the report that the first colored lady medical doctor has just passed the Alabama State Board and is qualified to practise medicine. The reports are modest in that the doctress is said to have passed with simply a high average. We trust that Doctress Dillon will be successful. The colored physicians the teaching of medicine ought to be entrusted to those who have made some special preparation for teaching over and above the mere college curriculum and a certain number of years of practice. All our larger academic institutions are surrounding themselves with a body of graduate students who, free from the petty tyranny of examinations, are pursuing knowledge for its own sake and for the power and influence it may give, and are not merely after a diploma. These men must, and it is proper that they should, present from time to time an original thesis, as a guaranty of their fidelity and as evidence of results accomplished. From their ranks the teaching force of our institutions is to be recruited.

zymotic diseases, 23.3 per cent. being from diarrhœal diseases, nearly one-fourth of the total urban mortality. Of 1,800 deaths occurring in rural districts, 28 per cent. were of children under five years of age, and 23 were from zymotic diseases, 18.5 being from diarrhœa. For the State these proportions vary little from the average for six years, the zymotic and diarrhœal mortality being a little lower than the average. Typhoid fever shows the usual increase, which always begins in August and continues through the fall months; the increase over July is chiefly in the maritime district, which ordinarily has a lower death-rate from this cause than other sanitary districts. There were fewer deaths from scarlet fever, measles, and diphtheria than in July, and a moderate increase from whooping-cough. There were more deaths than usual from accidents, chiefly from drowning and railway injuries."

Dr. Henry Bennett died recently at Mentone, aged seventy-five years. In his earlier years he was a pioneer in gynecology; for a long time he was one of the editors of *The Lancet*. Later, being obliged to go to the Mediterranean to live, on account of lung disease, he turned his attention to the subject of phthisis and its climatic treatment. His services in this line have been of immense value, and have saved or prolonged the lives of many invalids.

A Pæan in Honor of Æsculapius.—"De Novo Pæane in Honorem Æsculapii facto" is the title of a paper by Herr Ziebarth, of Göttingen, contributed to the "Commentationes" of the Seminarium Philologicum of Munich, just out. The ode, written in the dactylic metre employed for such compositions by the Greek tragedians, is addressed to Æsculapius by the town of Ptolemais, the modern Menshieh, in Egypt—addressed, moreover, on behalf of the Emperor Trajan, for the recovery of whose health the townsfolk vow to the god and his daughter, Hygeia, a restoration of their temple and glebe (τέμενος). Well engraved on stone and admirably reproduced by photography, the ode may be referred to the seventh year of Trajan's reign (A.D. 104), the "titulus" inscribed over it setting forth that Pompeius Planta was then Prefect of Egypt, as we know from one of Pliny's letters to the Emperor to have been the case. It is possible, however, as Herr Ziebarth suggests, that though published in that year the ode may have been written long before, as it follows closely on the lines of another "pæan," addressed to Apollo, reproducing the same invocation, the same prayer, and the same metrical form. As a specimen of official poetry it has much interest for the student of the history of medicine, as will be found by anyone who can give an hour to the admirable Latinity of Herr Ziebarth's paper.— *The Lancet.*

Professor Adamkiewicz, of Cracow, who has been making researches on the etiology and treatment of cancer, which he thinks likely to lead to highly important practical results, recently applied to the Austrian Minister of Education for permission to pursue his investigations in a larger clinical field than he can command at Cracow. The Minister has placed the material in the First Surgical Clinic of the Vienna General Hospital at his disposal for the purpose during the next winter semester. Professor Adamkiewicz has already begun work in the Austrian capital.

HEGAR'S EXTRA-PERITONEAL TREATMENT OF THE PEDICLE AFTER SUPRA-VAGINAL HYSTERECTOMY FOR FIBROIDS.

With Description of Chromo-Lithograph (Frontispiece).

(From "Pozzi's Gynecology.")

As the majority of authors do not classify their cases according to systems which permit comparison, it is difficult to decide as to the absolute mortality of the operation. However, in default of anything better, we must have recourse to statistics, and these show a decided percentage in favor of cases where the pedicle or stump is treated by an extra-peritoneal method similar to that shown in the accompanying plate. Pozzi, in his new and valuable treatise on gynecology,[1] after describing in detail the intra-peritoneal and mixed methods of disposing of the pedicle, and the application of the permanent elastic ligature, speaks of this method as follows:

"One of the most important points in Hegar's method is the complete isolation of the pedicle outside of the abdominal cavity. By suturing the peritoneum below the elastic ligature, and by non suture of the immediately adjacent abdominal planes, he forms a gutter which surrounds the pedicle so that it remains isolated like a pistil in the centre of a flower. This gutter prevents the pedicle, which is meant to slough off, from being imprisoned within the soft parts and infecting them, and about it we can make topical applications destined to mummify it and keep it aseptic. This peculiarity of the technique, especially in very stout patients, is of the greatest value. To . . . attach the peritoneum to the surface of the pedicle immediately below the ligature . . . I prefer catgut (Plate VI., Figs. 1 and 2).

"Great care must be taken that only the serous surface is included in this suture, using a very fine curved needle that the punctures may not bleed. It is well, with the same suture, to attach the stump of the broad ligament on each side to the stump of the uterus as closely as possible. When this peritoneal collar has been applied to the pedicle we may continue the suture of the peritoneum through the whole length of the abdominal opening with the same needle and catgut, adding, if necessary, a few supplementary points. The suture of the other abdominal planes is begun about 4 ctm. above the pedicle (Plate VI., Figs. 3 and 4).

"To prevent the pedicle from descending too far into the pelvis under the influence of movement, etc., two strong pins, crossing like the letter X, are passed through just above the ligature, and their pointed ends cut off. These pins have the additional advantage of preventing the elastic ligature from slipping. Below their ends small pads of iodoform gauze are placed to prevent their wounding the integument (Plate VI., Fig. 5). Then, with the scissors, the pedicle is trimmed to the shape in which it is to be left, and after surrounding it with wet antiseptic compresses its surface is charred with the thermo-cautery."

The dressing and after-treatment is then described, and the relative indications which should determine the choice of an extra- or intra-peritoneal method most clearly discussed.

Fig. 1.—The suture of the peritoneum to the lower part of the pedicle is begun; the pedicle being strongly drawn upward so that its distance from the pubes is much increased.

Fig. 2.—Suture of peritoneum about lower portion of the pedicle completed.

Figs. 3 and 4.—Suture of abdominal walls above the pedicle. (3) Continuous catgut suture of the peritoneum, and (4) of the musculo-aponeurotic planes.

Fig. 5.—Peritoneum sutured in a ring about the lower part of the pedicle, the stump being strongly depressed to show this suture. Deep sutures for integument in place, and superficial ones tied above the pedicle.

For the purpose of demonstrating the arrangement, and to allow movement of the stump, the wound is shown with the cutaneous sutures below the pedicle not yet in place.

THREE DIAGNOSTIC SYMPTOMS OF MELANCHOLIA.

Second Communication.

By LANDON CARTER GRAY, M.D.,

Professor of Nervous and Mental Diseases in the New York Polyclinic.

I read, in June, 1889, before the American Neurological Association, a paper with the same title as this,[1] detailing sixteen cases of melancholia in which either the three symptoms—melancholia, insomnia, and post-cervical ache—or some two of them were present. Since then I have had the opportunity of observing twenty cases of the same disease, and they have all been confirmatory of the position which I then took, namely, that these symptoms were of great diagnostic importance in the recognition of simple melancholia.

These latter cases are as follows:

Case I.—Male, aged fifty-five. First seen in November, 1890, when the melancholia had been present for about two and a half months. There was marked insomnia, distinct mental confusion, marked dulling of the cerebral reflex, but no post-cervical ache whatsoever, acute auditory hallucinations, and the melancholia was almost of the agitated form. This patient progressed very favorably in the course of six weeks, when he left for home still under treatment.

Case II.—Female, aged forty-three. Some ten years ago had an attack of melancholia lasting about a year, from which she recovered excepting some slight eccentricity and an inability to do the usual amount of mental work. This patient was first seen by me in August, 1890. The present attack had commenced in December and had been caused by great grief at the death of an intimate friend. There had been marked hallucinations and delusions for several months after the onset, and even when I first saw her there was a marked mental dulness with slight hallucinations. The insomnia had been obstinate and persistent from the start, and suicidal attempts had been frequent. In the previous attack there had been well-marked post-cervical aching, but there has been none in this. This patient recovered perfectly in the course of eight weeks, with the exception of her insomnia, which is apt to recur at present from time to time.

Case III.—Female, aged forty two. Has had very

[1] The Journal of Nervous and Mental Diseases, January, 1890.

vivid optical hallucinations, non-delusive for the last year. Melancholia almost of the agitated type. Has had obstinate insomnia and post-cervical ache for this period of time. This patient has improved greatly under treatment.

Case IV.—Female, aged thirty. Pronounced melancholia, with slight delusions and delusive optical hallucinations, obstinate insomnia, no post-cervical ache.

Case V.—Female, aged forty. Great melancholia, obstinate insomnia, and what she terms headaches running from the vertex down the back of the head to the nape of the neck, with auditory illusions and visual hallucinations. She had a previous attack some four years ago, since which the post-cervical ache has persisted, and has had occasional attacks of slight melancholia. Has no delusions whatsoever.

Case VI.—Male, aged twenty-nine. Has persistent insomnia, post-cervical and occipital aches conjoined with a feeling of constriction across the forehead. Has had constant suicidal impulses, which, however, he has been able to restrain perfectly, and a deep melancholy.

Case VII.—Male, aged twenty-five. For the past year has had constant headaches, starting in the left occipito-parietal region and extending over the whole head. Great melancholy and constant suicidal impulse. The insomnia has been very persistent and obstinate. Has no hallucinations or delusions.

Case VIII.—Female, aged twenty two. For two months has had steady pain in the frontal and also in the occipital region, and obstinate insomnia, and has been very greatly depressed. Has made several attempts at suicide.

Case IX.—Male, aged forty-six. Seen November 12, 1890. The duration of the disease has been eighteen months. Began with profound melancholy, to which was added, in the course of a few weeks, persistent insomnia and aching in the back part of the head and neck, although this location of the pain was only temporary at the onset as it is now at the vertex. Patient is very melancholy, shedding tears frequently without cause. Has occasional suicidal thoughts, but he states that these are very easily dispelled. There was considerable mental confusion until about three months ago, but he yet talks slowly and with a barely perceptible effort, although he is naturally quick in conversation. The memory has been fairly good for these eighteen months, although it has failed him temporarily in several important business matters. He looks very sad and depressed.

Case X.—Male, aged thirty-two. Was first seen September 16, 1890. Has had obstinate insomnia for four or five years, obtaining only four to five hours' sleep. Has had slight suicidal thoughts occasionally, these being very persistent upon two occasions. He admits that he has often felt that life was useless and has longed to get out of it. Has never had any hallucinations or delusions. Has had occasional attacks of slight mental dulness, and thinks that he has on several occasions had a slight dulling of cerebral reflex so that he would have to make a mental effort to follow conversation. He has a peculiar sensation in the occiput, running down into the neck, never ascending to the vertex, and which he describes as an odd feeling of numbness and tingling. He is a very bright, quick man, of fine physique, and has been extremely successful in large and complicated business operations. On October 31st this patient began treatment, and in this interval of time the insomnia had increased so much that for several nights in succession he obtained no sleep at all.

Case XI.—Male, aged fifty-six. First seen in October, 1890. This patient has had a melancholy tendency throughout life, and during the last year or more—the exact time cannot be stated—he has suffered from causeless depression; thinks he is spending too much money; sheds tears without cause; is very morose, moody; sleeps and eats well; is very much depressed about his real estate investments, although his wife assures me that there is not the slightest reason for any anxiety. He inherits a melancholy temperament; his color is good; has a slight tremor of the hands; has no hallucinations, so far as can be ascertained. When seen alone admits that he has not had a day for over a year without suicidal thoughts and longings, and has even gone so far as to purchase a revolver. Realizes, when reasoned with, that there is no reason for worry about property or himself. At one time in the course of the disease there was considerable mental dulness and a dreamy condition, but he thinks that his memory is perfect for all that occurred throughout his sickness. His melancholy is worse in the morning. Can derive no pleasure from any source. He has no post-cervical ache whatsoever at present. Had the grip last winter, and seems to have had an attack of cerebro-spinal meningitis some seven years ago.

Case XII.—Male, aged forty-two. First seen in October, 1890. In the spring of 1877 he lost seventy pounds in weight in a short time and was much depressed in health, with great thirst, vague nervous spells, anorexia, headache, drowsiness, and obstinate insomnia, all of which symptoms are said to have been due to diabetes, from which he now suffers. He now has considerable pain in the back of the neck, severe melancholy, and at one time vague auditory hallucinations when in a certain room; has marked delusion about the state of his business affairs, sheds tears very easily, has to make considerable effort in thinking, talks slowly. Has evidently been subject to migraine throughout his life.

Case XIII. — Male, aged forty-three. First seen September, 1890. For the last two days there has been an aching in the occiput down the shoulders, never ascending to the vertex. On the night before coming to me he had only two hours' sleep, and has suffered from a lesser degree of insomnia for several weeks before. Has had great depression in the last two days and has cried like a child, although he is naturally of a self-contained, virile temperament. The tears were caused by something said to him which hurt his feelings, although it was some trifling matter of business which would ordinarily not have affected him at all, and this nervous shock seems to have been the cause. The tongue is heavily coated with a yellow fur. He is of a constipated tendency, and has been much constipated in the last few weeks. No mental confusion has been noticed by himself or wife, nor any delusions or hallucinations. Has suffered from dyspepsia for about one year, and considerable flatulence three or four hours after meals. This patient was found to be suffering from inability to digest starchy foods and some coincident slight stomachic maldigestion. He recovered in a short time upon a nitrogenous diet, and the administration of pepsine, pancreatine, and naphthaline. His tendency to melancholy and slight attacks of insomnia have lingered, however, up to the present time, although they are readily corrected by attention to the foregoing dietetic and medicinal considerations.

Case XIV.—Male, aged fifty-five. First seen in March, 1890. Has been of melancholy temperament throughout life and subject to fits of depression. Has never suffered more than slightly from insomnia. Has lately had a feeling in the occiput running down between the shoulders, and consisting of what he terms vaguely a "wild feeling," so that he feels startled, as if, as he says, he were hysterical. This patient recovered in a few weeks and remained well throughout the summer. In the early autumn, however, he had another attack, attended with slight jaundice, the latter evidently due to a mild degree of duodenitis. When this was corrected his melancholy and post-cervical ache remained, and has continued more or less to the present time, its continuance being due, I think, to the fact that he is a very difficult patient to treat, as he ceases to come to me upon any slight improvement in his system. In these attacks he has a slight delusion about his affairs, so that he thinks himself poverty-stricken and about to lose everything, when in reality he is a man of ample means.

Case XV.—Female, aged thirty-two. First seen in June, 1890. Ten years ago, after a fright, this patient had an attack of melancholia lasting some two months, and has since then had three or four attacks, each lasting about the same time. The present attack has lasted since January, and began after reading a newspaper article about some man suddenly becoming insane. The melancholy in these attacks is generally causeless, lasting only a few minutes, and in them she has often thought of killing herself and her children, but has been able to readily dismiss these ideas. Has slight insomnia, consisting of restlessness for an hour or two before going to sleep. Never had any aches or pains about the head before this attack, but now has a pain in the occiput, occasionally creeping up toward the vertex, but never in the neck, and consisting of a sensation which she describes as "creeping" in the scalp rather than pain. She tells me that she gets very much confused mentally when she has the melancholy, but this I have not been able to see for myself. Thinks that her memory has never been impaired. There is a slight neurotic heredity, as her mother and sister have migraine, although she has never suffered from it herself. In other respects than these she is a thoroughly healthy woman, her digestion being especially good. She has a slight tendency to constipation. This patient recovered in a few weeks and went off to the country for the summer perfectly well, but has since had one or two slight attacks which have been easily checked by slight medication.

Case XVI.—Male, aged thirty-five. First seen in December, 1889. About eleven months ago this patient had some pulmonary trouble, accompanied by night-sweats, from which he fully recovered in five months. After this his present symptoms began. He has a fulness in the back of the head and around the ears, occasionally descending into the shoulders. For a few weeks past has had occasional insomnia. At first he had slight suicidal tendencies, in the last three or four years has had both suicidal and homicidal tendencies, which have been almost uncontrollable, so that one day he found it almost impossible to restrain himself from killing his little boy with a hammer. He says that death would be a boon to him. The melancholy has been much worse in the last three years. He is unable to obtain pleasure from anything. He cannot recall any period of mental confusion. Has been doing an extremely prosperous business during the last ten years, so that he is now a rich man, although he was not worth a dollar ten years ago. He has visual hallucinations; for instance, when sitting in my waiting-room felt that he could see a pair of feet raised in front of him, and in coming to me thought he saw some one being run over and shrank from the sight. These hallucinations are non-delusional. Seems to have no illusions or delusions. A careful cardiac and pulmonary examination revealed no organic trouble in these organs. In the last two weeks had only had two or three hours sleep at night. Has a marked precordial fear at times, although he is not much agitated by it. Has had occasional severe stomachic symptoms and indigestion, and has a chronic indigestion with eructations of odorless gas. His tongue is slightly coated. His appetite is good. Is constipated. Has had severe migraine all his life, inherited from his mother, but this has been made much better by the melancholia. He states that anything given for the "stomach" and "liver" has helped his head. Has no hereditary history although he comes of a family in which I have treated several members for epilepsy, migraine, and chorea.

Case XVII.—Male, aged sixty-seven. First seen in November, 1889. About two months ago this patient began to worry about the affairs of a college of which he was president, and became greatly depressed. Has had persistent and obstinate insomnia for the last month, so that he has not been sleeping more than two to three hours upon any night. Although this patient would not at the time of his sickness admit that he had any suicidal tendencies, I yet suspected them, because he cautioned his wife not to leave the nux vomica bottle in his room, and also because he had warned her that there would soon be a great catastrophe, and since his recovery, only a few days ago, prior to a long course of travel that he is now taking, he told me that his suicidal impulses were a great source of torment to him, so much so that, as he expressed it, he lived in hell, and that only the fact that he was a minister prevented him upon numberless occasions from taking his own life. There seems to have been no direct neurotic heredity, though insanity has run in some collateral branches of the family. The melancholy of this patient was so extreme as almost to be that of melancholia agitata. He would cry, wring his hands, moan, refuse to be comforted or to believe that there was anything in store for him but eternal torment, and, at times, became so agitated as to need the care of an attendant. Looks weary and emaciated. Pulse good. Tongue is heavily coated, has flatulence and anorexia, and has diarrhœic tendency. Has no post-cervical ache whatsoever. Is somewhat confused mentally, and his cerebral reflexes are dull. This patient made an excellent recovery in the course of four months, has since resumed his occupation, and has, as I have said, just departed upon a long tour of travel.

Case XVIII.—Male, aged thirty-four. First seen in October, 1889. The onset is said to have been after a cold bath this summer at Narraganset Pier. Has been very intemperate until about two and a half years ago. After the cold bath is said to have had an acute nephritis, as denoted by casts, blood, and albumin. An examination of the urine shows that it is now normal. Has since the nephritis had persistent insomnia, so that he claims he cannot now sleep without thirty grains sulfonal. Is very nervous and apprehensive. Is subject to slight cardiac palpitations. His appetite is good, but he is somewhat constipated. Has vague neuralgic pains throughout body, and also in the head when worried. Has no delusions or hallucinations. Has never had suicidal tendency. Has occasional drawing pain in the back of the neck and down into the shoulders. Three years ago had delirium tremens. This patient improved somewhat under a treatment conducted through four weeks, when he returned to his home in a distant city, and in the course of some six months made, I am told, a fair recovery and remained well for some nine months, when, under business strain and some slight intemperance, he had an attack of acute mania and was committed to an asylum.

Case XIX.—Female, aged twenty-eight. First seen in October, 1889. Sister and brother have had slight melancholia. The duration of this attack has been about one year. Has had constant pain in the occiput, at times quite severe. Has had great insomnia throughout the whole year. Has also had persistent melancholy, occasionally so marked that the patient would shut herself up in her room and weep and cry without cause, recognizing that there was no cause. There is absolutely no other disease than that indicated by these symptoms. There is a slight delusion that people regard her suspiciously, although she can readily be reasoned out of it. There are no hallucinations or illusions. This case was diagnosed as hysteria. She recovered in three months under careful treatment.

Case XX.—Female, aged fifty-two. Seen in November, 1890. For over a year she has been very melancholy and depressed. Has no post-cervical ache, and has had none. Has marked and constant insomnia. Her memory has been perfect throughout the sickness, except a short period at the outset. Has hallucinations of hearing which are semi-delusive.

These are the original cases which, as I have said, I reported in June, 1889:

Case XXI.—Female, aged thirty-five. Had a severe attack of melancholia five years ago, caused by the sudden death, by a fall from his horse a few days before the intended marriage, of the gentleman to whom she was betrothed. The melancholia lasted for upward of a

year, and it was not until about a year ago that she came under my care. She then complained greatly of obstinate insomnia and severe aching in the back of the head and neck. For three years this patient has been under my treatment, so that I have been able to observe in her the existence of a fixed melancholy, of such a nature that it seems utterly impossible for her to receive a pleasant impression of any kind. At times she has attacks of dull aching pain in the back part of the head, neck, and shoulders, and at the same time she becomes more or less sleepless. These attacks have usually been mild in character, and have yielded after about a week of treatment, but occasionally they have become very severe, and the post-cervical ache has become actual pain of considerable intensity, the insomnia has become pronounced, and the melancholic condition has deepened and has been attended with mental confusion and hallucinations.

Case XXII.—M——, widow, had attack of melancholia agitata about eight years ago, during which she made repeated and determined attempts at suicide. When I saw her a year or two after the acute symptoms had disappeared she had a fixed melancholy which no reasoning could influence; slept only three or four hours each night, and was troubled with a constant aching, uneasy feeling in the back of the neck and head, and in the shoulders. During the years that have since elapsed in which this patient has either been under my care, or so situated that I have known accurately of her condition, she has had almost uninterruptedly the fixed melancholy, the poor sleep, and the post-cervical aching. At times the insomnia has become very obstinate, and the post-cervical ache has mounted into severe neuralgic distress, but she has had no increase of her mental symptoms.

Case XXIII.—Female, married, sent to me September, 1888. She gave a history of a meningitis following insolation many years ago. During the 1st six months she has been suffering from melancholia, obstinate insomnia, slight hallucinations, and constant distressing aching in the back of the head and neck, and in the shoulders. Under treatment these symptoms disappeared, with the exception of some slight aching in the locality described, and the patient was doing very well when she was again sunstruck in the early part of the summer, since when I have lost sight of her.

Case XXIV.—Female, unmarried, had had melancholia for some two months, and had made two determined attempts at suicide. She had a causeless melancholy which could not be reasoned away, but had never had any hallucinations or mental confusion, had obstinate insomnia, and well-marked aching in the back of the head and neck, and in the shoulders. This patient has improved very greatly during the year that has since elapsed, I am told, but she still suffers from her melancholy, and occasional insomnia, but I have not been able to inform myself in regard to the post-cervical aching, as I have never seen her but upon the one occasion of the consultation with her attending physician.

Case XXV.—Female, aged forty. She has a causeless melancholy, slight hallucinatory tendencies, has talked longingly of suicide but has made no attempt at it; has suffered from obstinate insomnia, and has considerable distress in the back of the head. This patient refused to be treated, and I know nothing further accurately of her history.

Case XXVI.—Female, aged thirty-two. She had had slight melancholy, entirely causeless; had spoken about suicide, but never made any attempt at it; suffered from insomnia for about two weeks, and also from distress in the back of the head and neck. This case has made an excellent recovery in some six weeks under treatment of the attending physician, and when I saw her in consultation she was only suffering from the distress in the back of the head and from slight melancholy. This was altogether one of the mildest cases that I have ever seen in my life

Case XXVII.—Female, aged twenty-five. This patient had a severe attack of melancholia, with considerable agitation, obstinate insomnia, marked suicidal tendencies, but manifested no symptoms of the post-cervical aching. I attended her for some eight weeks, during which her condition did not materially improve, except that the insomnia was successfully combated with hypnotics. She then passed out of my charge; whether she afterward had a post-cervical ache or not, I am unable to say, or as to what her further symptoms were.

Case XXVIII.—Female, aged twenty. This was a case of mild melancholia agitata, with marked melancholia and melancholy hallucinations, and some slight mental confusion. This patient committed suicide in a most determined and seemingly intelligent manner by taking the poison known as "Rough on Rats."

Case XXIX.—Male, aged sixty-seven. This patient is suffering at the present time from melancholia, with marked suicidal and homicidal tendencies, slight hallucinations, and great insomnia, but has no post cervical ache.

Case XXX.—Male, aged thirty seven. Came to my office complaining of pain in the back of the head and neck. Something in the man's manner aroused my suspicions, and I found that he had, about six years ago, while living in Farther India, an attack of insomnia, slight mental confusion for a short time, and suicidal tendencies, all these symptoms having lasted about six months, and since this time he has had an aching post-cervically, which often passes away and leaves only a neuralgia over the left ear and scalp. This patient recovered.

Case XXXI.—Male, aged thirty-four. Is very melancholy and apprehensive, has obstinate insomnia, sleeping about four hours with large doses of sulphonal, and has a constant drawing pain in the neck and shoulders. No suicidal tendencies. This patient has recovered.

Case XXXII.—Female, unmarried, aged twenty-eight. For about a year has had constant and great insomnia, pronounced melancholy, occasionally becoming greatly agitated and so marked that she would shut herself up in her room and cry incessantly. Has constant pain in the occiput, which is at times quite severe. Has slight delusions.

Case XXXIII.—Female, unmarried, aged thirty. Great melancholy for the last six months, and obstinate insomnia for the same time. Has a weary aching feeling over the back and the top of the head. During the last ten years she has had several similar attacks, lasting two to three months, with insomnia, aching post-cervically and at the vertex. In one of these attacks she had a hallucination of sight, otherwise no hallucinations or delusions in any of these attacks. Has had suicidal ideas frequently suggest themselves to her, but has been able to repel them.

Case XXXIV.—Female, married, aged forty-two, wife of a physician, came to me complaining of great aching distress in the back of the head and shoulders. This led me to interrogate her closely, when I found that she had just recovered from an attack of typical melancholia with obstinate insomnia, marked suicidal and homicidal tendencies, which nothing but her strong religious feelings had enabled her to control, and which she had suffered for some six months without daring to tell her husband. This patient has recovered.

Case XXXV.—Female, married, aged thirty-three, sent to me by a physician. About nine months ago was attacked with melancholia shortly after severe domestic misfortune, suffered for three consecutive nights absolute sleeplessness, and then began to suffer from pain in the back of the head and down the spine. Since the onset the melancholy and the ache have been present almost the whole time, but the insomnia has been treated with fair success, although she still sleeps badly, and is a long time in getting to sleep. At first she had optic hallucinations occasionally.

Case XXXVI.—Female, unmarried, aged twenty-six. About one year ago, after great worriment and night work in nursing her mother, she began to be very sleepless, and to have an aching feeling in the back of the neck, and became very melancholy. In the last three months she has heard a constant crackling sound at the back of the head. Has never had the slightest suicidal feeling.

From the histories of these patients, thirty-six in all, it will be seen that the symptoms to which I have called attention were present with remarkable uniformity. It is a curious fact that all of them were cases of simple melancholia, and that they thus furnished additional proof of what I had stated in my first article, that the severer forms of that mental disease seldom had insomnia or the post-cervical ache. Every physician is well aware that melancholia can be classified into four types, simple melancholia, stupid melancholia, melancholia attonita, and melancholia agitata; and it is well known that the salient characteristic of stupid melancholia is, as the name implies, such mental confusion as amounts to stupidity, while the other forms are characterized respectively by a cataleptoid condition and great agitation. In all of these severer degrees the symptoms are so well marked that there is no difficulty in recognizing the cause of the mental impairment and the suicidal impulses. The lighter phases of the disease, however, are generally so ill defined that the general practitioner is apt to be puzzled, while even the neurologist may for a time be in doubt. Indeed, one can scarcely pick up a newspaper without reading an account of some suicide, frequently also of some homicide, of a patient who was supposed to be suffering from neurasthenia, and whose suicidal or homicidal act is satisfactorily accounted for, at least to the mind of the public, by some preceding love affair or some business reverse or disappointed hope or ambition. If, then, the three diagnostic symptoms to which I have called attention, insomnia, melancholia, and post-cervical ache, are present, either altogether, or in groups of two, in all these simple cases of melancholia, as I think my cases warrant me in assuming that they are, we have at our disposal a triad of symptoms of great diagnostic value. Let us analyze them in detail.

Of the thirty six individuals, in thirty-four the melancholia was accompanied either by the post-cervical ache or the insomnia; in other words, in only two was one or the other of these two latter symptoms lacking. In nineteen cases of the thirty-six all three symptoms were present, melancholia, post-cervical ache, and insomnia—namely, in fifty-three per cent. In seven the post-cervical ache was lacking, nineteen per cent. It is curious that the insomnia was lacking in only two cases, three per cent., and that in those two the post-cervical ache was also absent. It will also be observed that in certain of these individuals the melancholic symptoms are in close relation to intestinal derangement, and at first sight it would seem that the latter are the cause of the former; but the progress of these cases will show that both the mental and intestinal symptoms are due to the one underlying disease, melancholia, while any experience in treatment will furthermore demonstrate that remedies addressed to the digestive tract will have only a temporary and adjuvant effect on the melancholia.

Melancholia is different from mere depression of spirits, as can be seen if the patient is closely observed. Each melancholic individual has a peculiar facies, which it is difficult to describe, but which, as near as I can put it into words, consists of a slightly suspicious look, a sadness that is seldom lighted by a smile, and an evident effort in thinking. This last factor can usually be brought more distinctly into relief by a little careful questioning and attention, because it is due to a dull cerebral reflex. Ask a patient a question, for instance, then watch the face keenly, and it will be perceived that there is a perceptible interval between the reception of the asking sound and the answer, during which interval the expression is one of some mental effort, such as an ordinarily quick and healthy mind will only need to make when it encounters a mental problem of unusual difficulty. The patient is generally aware of this dull cerebral reflex, and confesses it by stating that he has to concentrate his mind upon the question asked him. If we realize that these cases of slight melancholia are not only slightly dulled in their mental operations but that they are also incapable of receiving a pleasurable sensation, we can understand why the facies should be thus peculiar. As a matter of fact, melancholiacs are, as Talleyrand said of the great Napoleon, unamusable, although to an extent of which Talleyrand perhaps never dreamed. It is through the different sensations that a human being receives his pleasure in life, such as the optic, auditory, gustatory, olfactory, tactile, temperature-bearing, and muscle-sense-bearing, as well as through the different visceral sensations coming from the sexual and other internal organs of the body; but a melancholic, suffering from a cellular disease of the cortex, whose exact nature is as yet unknown to us, receives only unpleasant or even painful sensations through all these different nerve-tracts, so that it is as impossible to give pleasure to such a melancholic cortex as it is to refract unimpaired in its color a ray of yellow light through a pane of blue glass. While the same thing is true in varying degree of mental depression due to many other diseases than melancholia, it is never to be observed in such totality. Out of the warping influence of this melancholic cortex, too, springs the suicidal impulse which is so marked a feature. An almost universal expression with this class of patients is that they have been through hell, and I have time and again heard even ministers of the gospel, ordinarily choice in their language, make use of this expression with no profane intent whatever. Still, it is by no means always easy to obtain a clear history of the extent of the melancholia until the full confidence of the patient has been gained, and even then they are very prone to deny the suicidal impulse to which they may freely confess when they have convalesced.

The post-cervical ache does not always consist of aching, and yet I have not intended any paradox in so naming it, but I have selected this somewhat indefinite term because patients find it so difficult to describe the peculiar sensation, which is apt to vary in each case. One will speak of it as a "drawing," another as something uncomfortable, another as actual pain, another as vague aching, another as a fulness, another as a "creeping," another as a wild feeling that startles him and makes him feel hysterical, another as a numbness and tingling, while in some few it may consist of actual fibrillary twitching with an accompanying vague muscular sensation. In most cases this post-cervical ache disappears upon full recovery, although it is apt to recur for years afterward whenever the patient's general health becomes impaired, or it may have a sequelæ of neuralgic attacks, one of my patients, curiously enough (Case XXX.), having had a neuroma form upon one of the nerves implicated. In the imperfectly treated cases, however, this post-cervical ache is very apt to be persistent and to cause great distress for many years.

The insomnia varies greatly in degree. In some cases it may be so great that the patient will only obtain an hour or two of sleep for months, while in others it may only cut off a few hours of the usual slumber, or even occur only from time to time, or for a short time after the onset. Usually it persists for months after the other symptoms have disappeared, and, if not properly treated, it may last for years, as in Case XI., where it had made life miserable for five years; indeed, I attach so much importance to this symptom that I never consider a patient cured until the tendency has been thoroughly eradicated. In some few cases, however, it happily disappears with promptness and does not return.

By means of these three symptoms, therefore—melancholia, insomnia, and post-cervical ache—I feel certain

that we can differentiate cases of simple melancholia from all other forms of disease. Let me say just here, in order that there should be no confusion about my position in this matter, that I do not claim for these three symptoms separately the diagnostic value which I do claim for them when grouped together. We should never forget that just as we have so many letters in our alphabet from which in varying combination are formed the different words that constitute our language, so have we so many symptoms in medicine which can be readily catalogued and from the varying combinations of which we make our diagnoses of the different diseases, and that, just as the individual letter is of small importance, so is the individual symptom of relative insignificance. Melancholy can be excited by many causes, such as our late influenza, typhoid fever, great emotion or pain, hysteria, and neurasthenia, in which latter the most frequent type presenting it is that which occurs after railway accidents and other traumata. But in none of these, if I may trust my own experience, does the melancholy patient have the peculiar facies, compounded of the organic sadness and dull cerebral reflex. Insomnia, too, is observed in many diseases, especially those of an asthenic nature, and from worry, the emotions and the passions, but in these types it is not apt to be persistent, it is readily relieved, it is not accompanied by the peculiar melancholia which I have attempted to describe, nor by the suicidal impulses or the post-cervical ache. The post-cervical ache—bearing in mind, of course, what I mean by this arbitrary term—is also observed in the different forms of neurasthenia, in so-called spinal irritation, in hysteria, and occasionally without recognizable cause; but in these instances there is no attendant insomnia or melancholia

NOTE.—Since writing the above, my friend and former pupil, Dr. S. Grover Burnett, of Kansas City, Mo., has confirmed my observations in several cases. ("The Diagnosis of Incipient Melancholia," *New York Medical Journal*, May 2, 1891.)

6 EAST FORTY-NINTH STREET.

THE MAMMÆ AND THEIR ANOMALIES.

By T. J. McGILLICUDDY, M.D.,

INSTRUCTOR IN OBSTETRICS AT THE NEW YORK POLYCLINIC; OBSTETRIC SURGEON TO THE NEW YORK MOTHERS' HOME MATERNITY HOSPITAL; SURGEON IN CHARGE OF THE YORKVILLE DISPENSARY AND HOSPITAL FOR WOMEN AND CHILDREN, ETC.

COMPARATIVELY little has been written upon anomalies of the breast; indeed, in many obstetrical works they are not even mentioned, and in the writings of those who have investigated these conditions we find many contradictory opinions regarding their frequency and location.

It has been noted that the mammæ are in many cases of unequal size. The left is said to be often larger than the right. And the condition is accounted for by the fact that the left breast is more commonly used during lactation, the greater facility with which the child is held on the left arm, allowing the right to remain free to attend to any manipulation not requiring both hands. Still the opposite condition is also stated as the more frequent, and it would seem reasonable that the right breast should be the larger, partaking, as it must, of the general increase of volume of the right side over the left. A case is reported where both breasts were congenitally absent. This condition and the absence of a single breast is very rare, though there is a case on record of absence of one breast, said to have resulted from a maternal impression; the mother was frightened during the third month of pregnancy by a beggar exposing scars after removal of the gland for cancer. Mammæ of infantile size in the adult are generally accompanied by some ovarian defect or absence of these organs, while a too early and too great development of the breasts, of which several cases are noted, accompanies precocious development of the sexual organs. I am aware of such a condition existing in a young lad, and also in a girl of nine years of age who is menstruating. Among the curious anomalies reported is a case in which milk-secreting organs were developed immediately below each other on the upper part of the abdomen. I have also to report a similar growth of mammæ in a male (Fig. 6).

It is related that the fact of Anne Boleyn having a third breast was the reason Henry VIII. had her put to death.

Polymazia is much more frequently found than amazia, and polythelia or supernumerary nipples is said to be quite common. Rudimentary mammæ and nipples occur, according to some writers, once in every five hundred persons, and others state that they are found even more frequently.

FIG. 1.—After Sutton.

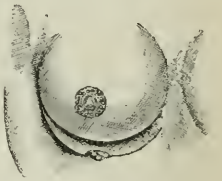

FIG. 2.—After Sutton.

These excesses of formation have been looked upon by theorists as a return in the direction of an earlier type, or a condition of atavism. Meckel says the earliest of our species had five mammæ, two pectoral, two axillary, and one near the navel. Isis, a goddess of the Egyptians, is sometimes represented as having but one breast and at others as having several. Diana, of Ephesus, is also represented with several breasts, typifying bounteous nature. Extra mammæ are most frequently found in the axilla or below the normal site, or they may be placed in the groins, on the thigh, or on the back. A writer of note states that most supernumerary glands are placed below and internal to the normal situation, and very rarely in the axillary space. Others look upon the axilla as one of the rarer situations for this anomaly. One author denies that they exist on the abdomen, but records five cases of axillary mammæ. Another observer has seen none in the axilla.

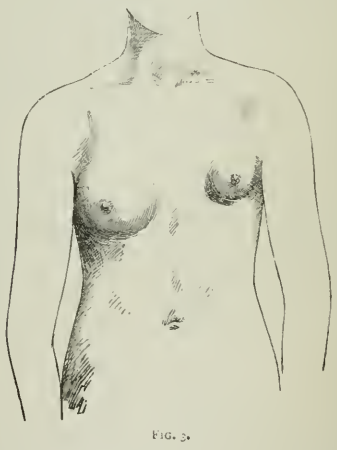

FIG. 3.

The axillary glands may have a nipple, or only a minute orifice, or the milk may exude through several minute canals. The case of a girl is reported with a nipple on her face below the lobe of the right ear. It had an areola and increased in volume during menstruation. After removal the microscope determined the true character of the growth. A case where a supernumerary mamma existed in the labium majora has also been reported.

The number of these supernumerary organs may vary

from one to half a dozen. An instance is reported of three brothers having four breasts each A supernumerary breast may have no nipple, but its secretion will ooze through the skin. Hypertrophy of the nipple alone is exceedingly rare, but they have been seen as large as an egg. I have had a case under observation where they were too large in diameter for the infant's mouth, making it impossible for the child to suckle without an artificial nipple. A breast may have two nipples, both secreting milk (Fig. 1). Absence of the nipple is very rare, but imperforate nipples much less so. In November, 1890, I attended Mrs. F—— during her second confinement. In neither of them was she able to nurse the infant, and although on both occasions the breasts filled with milk, none came through the nipple. This was probably the result of an inflammatory condition when she was an infant, as painful swelling of the breasts is frequently seen in the new born. It usually lasts, however, but a short time. Sometimes a little milk and a viscid fluid can be expressed from the nipples. Imperfect development of the breasts is not infrequent, and examples of primiparæ, especially of American nationality, who cannot nurse their offspring are frequently met with. These women may, however, after subsequent pregnancies, have an abundant supply of milk. The failure is the result of tardy development of the glands. Some fifteen cases of polymastia are reported in American medical literature.

Fig. 4.

Supernumerary nipples and mammæ are described as more common in men than women, and supernumerary nipples in men are said to be of extreme frequency. When we see a bifid nipple (Fig. 1), or two separate mammæ coalesced with two separate nipples (Fig. 2), we know that the anomaly is due to division of the gland germ, or dichotomy. It has also been maintained that the favorite situation for supernumerary mammæ is the axilla, where they may be found with or without nipples. The skin of the axilla in parturient women frequently presents enlargements which may attain the size of a hen's egg. Such enlargements do not possess ducts or pores, and usually, it is stated, attract attention about three days after labor. They increase in size with the breasts, but as a rule diminish in about two weeks after delivery. They are limited to the axillary region covered with hair, and may be made occasionally to furnish milk on pressure, but do not exude spontaneously, thus differing from two of the cases which I shall report.

Cases are recorded of supernumerary nipples with ducts or pores, from which, after delivery, milk and colostrum could be expressed. In some few cases the axillary glands are really continuations of the lobules which are prolonged outward beyond the limits of the breast. One observer, in post-mortem examinations of axillary mammæ, found a cord like prolongation only once in fifteen cases.

Fig. 5.

In lateral curvature of the spine, it is said that there is a marked difference in the development of the breasts—the one on the flattened side is always much smaller than the one on the protruding side. In the following case the patient's spine is perfectly straight.

Case I. (Fig. 3).—Mrs. G——, aged twenty-six; very anæmic; right breast and pectoral region at least one-half larger than the left. She ascribes this condition to the fact that she nursed much more frequently from it on account of the left secreting a too scant supply of milk. There is a very marked difference in the loudness of the respiratory sounds on both sides, which may be due to the difference in the thickness of the chest-walls, the left side being very flat.

The following case of supernumerary mammæ occurred in my practice.

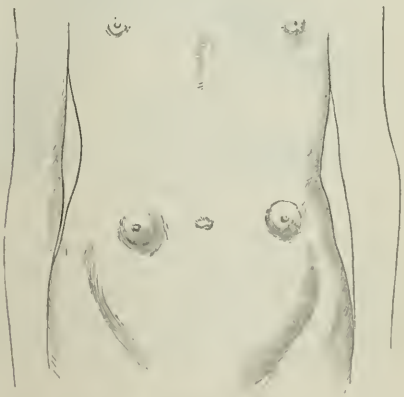

Fig. 6.

Case II. (Fig. 4).—Mrs. MacA——, aged twenty-four; well developed physically; health has always been excellent. At her second pregnancy, and on March 3, 1891, after an easy labor, she was delivered of a strong, perfectly formed infant. About the third month of her pregnancy the axillary glands had filled with milk; before that they were perfectly flat, and gave her no inconven-

ience. On examining them carefully, I found a large brown supernumerary areola situated in each axilla, of a lighter shade than that on the breasts, but no sign of a nipple. The milk, which flows continuously, but most freely while she is nursing, exudes through the pores of the skin, and can be readily seen as it starts and wells up from the minute orifices. It is thick, strongly alkaline, and contains colostrum corpuscles. The condition is very disagreeable to the patient, as it keeps her clothing constantly wet and stains it.

Case III. came under my observation through the kindness of Drs. Murphy and Fitzgerald. Mrs. E——, aged nineteen, is well developed and has always been in good health. Has had two children; the first was bottle-fed. Her second pregnancy terminated on March 8, 1891. Nothing unusual was noticed until four days after labor, when she found milk flowing from the left axilla. On examination two large orifices were seen, with two or three smaller ones in the same region. They exude milk constantly, but "twice as fast when nursing." The milk would soak through her dress and jacket, leaving a yellowish stain.

Case IV. (Fig. 5).—B. B——, aged twenty-six; single; of nervous temperament. A supernumerary gland on her right side was first noticed at her birth. Her menses first appeared at fourteen, and she has had pain in all three glands during her menstrual periods. Two years ago all the mammæ increased in size simultaneously. This supernumerary gland has been subjected to the pressure (often extreme) of a corset for fourteen years. It now extends from the seventh to the ninth rib, and has an oval shape following the intercostal space. For this case I am indebted to my friend, Dr. M. C. O'Brien.

Case V. (Fig. 6).—Mr. B——, aged thirty-five, entered the Harlem Hospital for the treatment of a fractured patella. An extra mamma was observed on a line with the navel, and another a little below it. The nipple of the one on the left side is four and a half inches from the umbilicus, while the other is but three inches from it. Under microscopical examination the secretion of the glands was found to be milk with a large proportion of colostrum corpuscles.

Case VI. (Fig. 7) is from a photograph of the case of Mr. Charles J. D——, aged forty-six. This man has

Fig. 7.

a supernumerary gland which is in the posterior portion of the left thigh, just below the gluteo-femoral fold; his sister states that it was first noticed at birth It is as large as the normal breast of a young woman, and its lobular structure can be distinctly determined on manipulation. On its surface are seen large blue veins, but there is no areola and the skin on the nipple is perfectly smooth.

Case VII. is that of a young man who has a perfect but diminutive supernumerary nipple, placed about two inches below the normal nipple of the left side, and slightly nearer the median line.

Case VIII. (Fig. 8) shows the location of a supernumerary gland in a child. Rosa R——, aged seven weeks, was brought to the clinic of Dr. M. R. Richard, through whose kindness I obtained the case for observation. There was nothing abnormal noticed at birth, and it was while examining the infant for another condition that the doctor discovered the nipple. It is slightly larger than the normal ones, and its location is very uncommon.

The notes of the two following interesting cases were obtained through the courtesy of Dr. Leonard S. Rau.

Case IX.—Miss R——, aged twenty-six; neurasthenic temperament; is very delicate and frequently hysterical. In this case no glandular development whatever can be detected; the condition is the same as in the male breast, nipples alone existing.

Case X.—Miss F——, aged eighteen. When thirteen years old was supposed to have been struck in the right

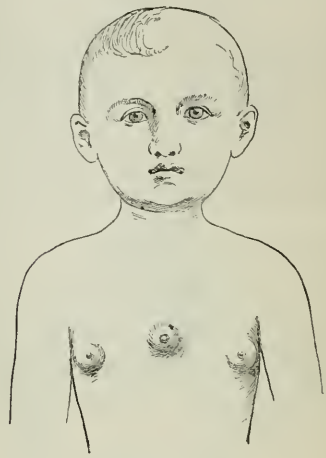

Fig. 8.

breast by her sister; shortly after that the breast began to develop rapidly, until it reached the size normal to a young woman of twenty; the other breast remained undeveloped. She was seen by a number of leading physicians of this city, and an eminent surgeon pronounced the condition one of Paget's disease, and advised removal of the breast. At present the breasts are normal and of the same size. Her menstruation is regular, and there is no uterine disease.

The following case is of interest in connection with the subject. John McV——, a lad of about fourteen years, was sent to the writer by a physician. The patient was suffering from excessive tenderness and tumefaction of both mammæ—a genuine mastitis. Its causation I could not learn. The lad is apparently perfectly healthy, and the history and examination gave negative results.

The preceding cases of anomalous conditions of the mammæ have, so far as I can learn, never yet been reported. The probability of glandular tissue in these situations undergoing a malignant change has been suggested. I see no reasons why it should occur, as the growths are simply excess of normal tissue. Operative interference, and the propriety of removing them, is a question that must rest entirely with the patient. It should not be urged by the surgeon. The writer does not believe it indicated under ordinary circumstances. The operation would, of course, be simple and safe, but the condition is merely an inconvenience when the glands are secreting, and will cease at the end of lactation, and the patient need only wear suitable clothing during the process. The presence of many of these anomalies is generally not suspected, and they are usually only discovered during lactation.

NOTES ON SOME RECENT METHODS OF STAINING FOR THE NERVOUS SYSTEM.

By JOSEPH COLLINS, M.D.,

NEW YORK.

One of the most fruitful methods of making important progress in the comprehension of the anatomy of the nervous system and the various pathological changes to which it is subject is unquestionably by discovering new methods of staining and perfecting old. Among the recent contributions in this direction I wish to speak of a few that have given very satisfactory results in my hands. These are Weigert's modification of his well-known hæmatoxylin stain, the so called methylene blue method, and Ramon y Cajal's modification of Golgi's sublimate method.

Professor Weigert has recently made public[1] an important modification of his excellent alcohol hæmatoxylin stain for medullary sheaths, which dispenses entirely with the necessity of differentiation. I was permitted to experiment with this stain in Professor Weigert's laboratory before and since he communicated it, and can safely say that it has always given most satisfactory results. The technique of the method is as follows:

The tissue is hardened in Muller's fluid and treated in the usual way with eighty five per cent. alcohol and then an equal time in absolute alcohol and afterward for a similar period or longer in celluloidin and then embedded on cork. Then comes the coppering, which is one of the important steps in this method. The embedded pieces are allowed to float for twenty-four hours in a mixture of equal parts of a seven to ten per cent. seignette solution (tartarated soda) and a cold saturated solution of copper acetate which is kept at an equable temperature of 38° to 40° C. in an incubator. They are then transferred to a mixture of equal parts of a similar solution of acetate of copper and distilled water and allowed to remain for twenty-four hours, also in the incubator. The pieces then remain in eighty per cent. alcohol until cut.

The next important point to bear in mind in order to get good results is that the sections should be cut very thin, otherwise the differentiation will not be sharply defined.

The staining fluid is composed of 1 part of the ordinary alcohol hæmatoxylin solution (1 to 10), as used for the old method, and 9 parts of a water solution of lithium carbonicum, or, as ordinarily prepared, 5 parts of the former to 45 parts of the lithium solution. It should be noted that this mixture must be freshly prepared each time as needed. The sections are allowed to remain in this fluid for from four to twelve hours, a longer period does no harm, however, as I have frequently left them in it twenty-four hours, with excellent results. They are then thoroughly washed in distilled water, dehydrated in ninety per cent. alcohol, and clarified first in anilin xylol (2 to 1), and afterward in clear xylol and mounted in xylol balsam. In some cases when Canada balsam is used as a preservative in which there is an excess of turpentine or ether a fading of the color will take place gradually and completely destroy the specimen. Therefore one should exercise a care that the xylol balsam used is of the purest. This modified method may be used for all the purposes of the old with the exception of celluloidin series and thick specimens. In these it may be used, but differentiation must then be done in the ordinary way.

In some conditions where it is desirable to have the groundwork particularly light the preparations can be washed in a very weak solution of acetic acid (one fifth to one half per cent); but it is found quite sufficient as a rule to allow them to remain in distilled water somewhat longer than ordinarily to bring them to the paleness desired. The advantages of this method of staining are that it dispenses with the tedious process of differentiation; it brings out more distinctly than the old the finest medullated fibres and the distinction between these fibres and the cells and other components of the tissues are more plainly marked. In preparations from the cortical substance of the cerebrum, for instance, where the ordinary hæmatoxylin stain is not always reliable, this method has succeeded admirably with well hardened and well-coppered tissues. In pathological conditions and in studying the anatomy of the nervous system in the lower animals it has also been very satisfactory.

The technique is in no way more difficult than in the ordinary method if a bit of care is taken that tissues are well hardened and properly coppered.

Professor Weigert does not put the modified method forward in order that it may supplant the old, but with the belief that it will prove simpler and more serviceable in some conditions.

The methylene blue method, which has been so carefully studied by Ehrlich, Mayer, Retzius, and others, is a method by which our knowledge of the peripheral nervous system has been very materially augmented and one by which many as yet very dubious things will be elucidated. It consists of injecting a solution of methylene blue into the body of a living animal or into the tissues of a recently removed part, and based upon the now known fact that this agent colors alone the fine distributing fibres of the nerves, their communicating ganglia and their endings. The solutions are made from rectified methylene blue, prepared by Dr. George Grübler, of Leipzig and put up in gramme packages designated as Ehrlich's and Mayer's, and I have succeeded in my experiments equally as well with one as with the other. The strength of the solution advised by Mayer is one gramme of the color to 300 to 400 c.c. of a one-half per cent. solution of sodium chloride. This is injected directly into the circulation, as into the jugular of the rabbit, or simply into the tissues. In the frog it is convenient to inject it into the lymph-sac or the venæ resp. mediæ. And in earthworms, with which I have worked somewhat with a view to determine their exact innervation, and which I expect to publish later, I have injected it directly into the body of the worm after the earth contained in them had been removed by feeding them on blotting-paper for a few days. Professor Mayer tells me that he has often injected it into the vein of a recently amputated part and secured very satisfactory results.

The amount injected varies of course with the size of the animal, but I find that from 6 to 8 c.c. is generally sufficient for a frog, and if more be injected there is danger of the animal's death before sufficient time has elapsed for the coloring process to take place, which generally takes from one to three hours. Mayer also says that the coloring can be brought about by allowing frogs to live in a moderately weak solution for several days, but my experiments in this direction were made with, as

[1] Wanderversammlung der Sudwestdeutschen Neurologen und Irren artze zu Baden Baden, June 7, 1891.

I afterward found, a poor preparation of the color stuff, so I was unable to confirm this.

A few hours after an injection the animal is killed and the tissues examined at once, for although the coloration of the nerve-fibres is at first intensified by being exposed to the air it soon begins to fade. If the experiment is successful the nerves distributing to the peritoneum, bladder, muscles, etc., with their interlacings and ganglia will be seen stained a remarkably distinct blue, especially the single and spiral nerve-fibres, the nerve fibrillæ, etc. In this way I think I have often seen the nerves supplying the sense of taste to the tongue ending directly in the taste-corpuscles.

The great difficulty attending investigations with methylene blue thus far has been the disappearance of the coloration after a short time. Many experiments have been made with a view of preventing this, and although thus far no absolutely reliable agent has been discovered, the one that succeeds best is by use of the solution designated as Mayer's pikrate of ammonia glycerine solution, made by taking equal parts of a concentrated watery solution of pikrate of ammonia and glycerine. After making the preparation by teasing, a few drops of this solution are allowed to flow over it, and then covered with a cover-glass. Professor Mayer has recently shown me some preparations that he has succeeded in preserving in this way for a long period, and they appear to show the results to-day as well as at first.

The importance of this method is at once apparent in showing the peripheral distribution of nerves, the ways of union by nerve filaments, their interlacings, their relations to ganglia, and the structure of the nerve itself. Any one specially interested in this method of work will derive great help, and also see what excellent results can be obtained, by consulting the magnificent work of Retzius, now being published in parts, termed "Biologische Untersuchungen."

A stain that has now passed the probationary period and placed itself on a permanent foundation of usefulness is the one known as Ramon y Cajal's, a modification and improvement of Golgi's nitrate of silver and sublimate staining. By Cajal's method the process is much shorter and the results far better and more certain than by Golgi's.

The technique is as follows: Small pieces of the central nervous system, embryonal or otherwise, are hardened in the following solution:

3 per cent. solution potassium bichromate	20 parts.
1 per cent. solution osmic acid	5 parts.

Or the mixture may be made up of

Potassium bichromate.....	3 parts.
1 per cent. solution osmic acid	25 parts.
Aqua destillat.....100 parts.	

The tissue is allowed to remain in this solution for twenty-four to thirty-six hours, in the dark, and changing it after a few hours will be of advantage. This process of hardening is of greatest importance, for if it is insufficient the deposit of the silver salt later will be in the shape of a granulous precipitate; while, if the hardening be too great the deposit does not take place at all. As a rule, twenty-four hours is quite sufficient for small bits of embryonal tissue, but larger pieces and those taken from grown animals will require forty-eight. When the hardening has been quite right it will be found that the silver nitrate deposits itself in extraordinary fineness in the nerve protoplasm, and presents a wonderfully distinct picture.

After the hardening the tissues are subject to the following solution: ¾ per cent. argentum nitrate, and in this they remain for twenty-four hours. The cutting is then done free hand, or on a freezing microtome, but as one of the important factors is to have the preparation thick, the free-hand method is advisable. The preparations come first in 40 per cent. alcohol, and afterward dehydrated for a very short period in absolute alcohol and cleared rapidly in oil of cloves and preserved in xylo or dammar balsam without a cover-glass. Or the preparation may be placed on a cover-glass fixed in a small wooden frame for the purpose, and then after the balsam has hardened it can be examined from the side of the cover-glass. Or the preparation may be placed on a slide and covered with a cover-glass, supported by legs of sealing-wax; but for weak magnification simply laying the sections on a slide in Canada balsam is quite sufficient.

In this way one can get remarkable pictures of the cell-structure of the brain and cerebellum in a few hours, whereas with Golgi's method the hardening alone takes from six to eight weeks for his sublimate stain. It is particularly in the great brain and cerebellum that the cells and periganglionic spaces show the deposit of the silver salt, but Riese has recently shown that also in cord and other parts of the central nervous system this method is of great importance and value. A full reference to Golgi's method and its literature may be found in a paper by Riese, of Freiburg, published in the *Centralblatt für Allgemeine Pathologie*, for June 15, 1891.

Clinical Department.

A CASE OF AMPUTATION AT THE HIP-JOINT BY WYETH'S METHOD—DEATH.[1]

By J. D. THOMAS, M.D.,

PROFESSOR GENITO-URINARY AND VENEREAL DISEASES, WESTERN PENNSYLVANIA MEDICAL COLLEGE, PITTSBURG, PA.

On Friday, July 31st, G. S——, a young man, aged eighteen, while working in front of a train of rolls in one of our rolling mills, as "catcher," failed to grasp with his "tongs" the red-hot bar, half an inch in diameter, as it came through. The end of the bar, however, struck his tongs and became slightly curled, then it struck and penetrated the left thigh of the patient about two and a half inches below Poupart's ligament, going through the long saphenous vein, the femoral vein and femoral artery. The hole produced was large enough at its entrance to admit two fingers, deeper but one finger could enter and this finger passed some distance around the inner and posterior surfaces of the femur, the curl in the bar causing the wound to take this direction. At the inquest, held after the death or the patient, one of the workmen testified that the amount of blood lost caused the place to look like a slaughter-house.

The patient was first seen by Dr. J. M. Duff, who placed a compress and bandage immediately over the wound and had him sent to the South Side Hospital, where I saw him. The patient presented a deadly pallor, rolled his head from side, and was absolutely pulseless. His condition was such that operative measures were precluded at this time—indeed, death appeared imminent. All that could be done was to prevent further bleeding. While removing the compress the artery above was controlled by digital pressure, this also gave the opportunity to make the above diagnosis. It was observed that when the compression over the artery was relaxed a little the bleeding came chiefly from the proximal end of the femoral vein and not from the artery; this could in part be accounted for from the empty condition of the arterial system. The wound was packed firmly from the bottom with a long strip of iodoform gauze and over this cotton and a loose retentive bandage were placed. The patient was then put to bed and heat applied to the limb. In the meantime stimulants had been given hypodermatically.

By Sunday, August 2d, as the patient had rallied pretty well it was deemed advisable, although the limb was still warm and no gangrene had taken place, to proceed to amputate at the hip-joint. To this the parents of the

[1] An unreported case of amputation at the hip-joint, proving fatal, was done by me in 1880 upon a boy, aged twelve years, following a railroad injury.

boy absolutely objected, although the patient himself was willing and desirous to have the operation performed. Under the circumstances all that could be done was to re-dress the wound. The patient was placed under ether, compression made over the femoral artery and the packing removed. With slight relaxation of the pressure it was patent that closure of the vessels had not taken place. I then cut down upon and ligated both femoral vessels. As the vein was directly under the artery at the seat of operation, for fear that the ligature was not properly placed here, the end of the vein was grasped with a pressure-forceps which was left in the wound with the other dressings. For twenty-four hours after this operation the boy did fairly well, although complaining of pain in the limb. The second day following, the pain in the leg became more severe and some œdema had taken place. On the third day a slight discoloration appeared and on the fourth day began to spread upward toward the knee. After considerable persuasion the parents consented to have the limb removed, as they saw that the gangrene was slowly approaching the body. On August 6th, at 2.30 P.M., with the assistance of Drs. Arnholt, Duff, Burleigh, and other members of the staff, I amputated at the hip-joint, according to the method of Dr. Wyeth, with the exception that an Esmarch bandage was not applied. The Esmarch was not applied for two reasons, first, as the veins through which the blood returned to the body had been severed during the accident it would be useless, and second, as the limb was gangrenous septic matter might be forced into the circulation.

The directions for performing this operation after the Esmarch is applied is as follows, viz.: "Two steel mattress needles, three-sixteenths of an inch in diameter and a foot long, are used. The point of one is inserted an inch and a half below the anterior superior spine of the ilium, and slightly to the inner side of this prominence, and is made to traverse the muscles and deep fascia, passing about half-way between the great trochanter and the iliac spine, external to the neck of the femur, and through the substance of the tensor vaginæ femoris, coming out just back of the trochanter. About four inches of the needle should be concealed by the tissues.

"The point of the second needle is entered an inch below the level of the crotch internally to the saphenous opening, and, passing through the abductors, comes out about an inch and a half in front of the tuber ischii. No vessels are endangered by these needles. The points are protected by corks to prevent injury to the operator's hands.

"A piece of strong white rubber tube, half an inch in diameter and long enough when tightened in position to go five or six times around the thigh, is now wound very tightly around and above the fixation needles and tied.

"The Esmarch bandage is removed, and five inches below the tourniquet a circular incision is made, and a cuff, which includes the subcutaneous tissues down to the deep fascia, is dissected off to the level of the lesser trochanter, at which level the muscles and vessels are divided squarely and the bone sawed through.

"All vessels (including the veins) which can be seen are tied with catgut, and the smaller bleeding points can be discovered by slightly loosening the tourniquet, which is then entirely removed.

"The remaining portion of the femur is now easily enucleated by dividing the attached muscles close to the bone and opening the capsule as soon as it is reached. On lifting the end of the bone in the direction of the patient's navel, and dividing the cotyloid ligament posteriorly, the air enters the cavity of the acetabulum and greatly facilitates the division of the ligamentum teres."

In my case the vessels were occluded by twisting. The remaining portion of the femur was enucleated by first making an incision along the outer side of the bone up to the acetabulum, then it was rapidly freed, with a scalpel, from all the soft tissues, the capsular ligament was severed for some distance parallel with the rim of the acetabulum, when air rushed in and made the severing of the ligamentum teres a very easy matter.

Taking into consideration what the patient had gone through, his condition after the operation was excellent, and so remained until the morning of the 8th, or for thirty-six hours, when he began to fail rapidly, and died about 8 P.M. from exhaustion.

The result might have been different had the amputation taken place on August 2d. As the patient was a minor he had no legal authority to permit the amputation to take place, neither had the hospital staff any authority to do the operation so long as the parents objected. In other words, the law permits the ignorant to dictate to the surgical staff of a hospital when an operation shall be performed.

There are two points in the technique of the operation which I desire to notice. According to the directions the outside needle is to be introduced one and a half inch below the anterior superior spine of the ilium, and slightly to the inner side of this prominence. By bringing the needle "slightly to the inner side" it is brought close to Poupart's ligament and a little too high for the coils of rubber tubing to press immediately below this ligament, which they must do to be efficient. This is exactly what happened in my case, but as the femoral vessels were already ligated it made no difference. I think this miscalculation can always be avoided by first laying the rubber tubing over the artery at the proper place below Poupart's ligament and then using the lower border of the tubing as our guide, regardless of the spine of the ilium. The other point is to clear the bone of all tendinous and other soft tissue connections before attempting the disarticulation at the joint.

DIPHTHERITIC CONJUNCTIVITIS TREATED BY CONTINUOUS ANTISEPTIC IRRIGATION.

By E. L. OATMAN, M.D.,

NYACK, N. Y.

In the spring of 1885 an epidemic of purulent conjunctivitis was prevalent in one of the asylums for children situated in this county. There was coincidently developed in the same institution a fatal type of diphtheria.

Lizzie M——, aged ten, while convalescing from a severe attack of the latter disease, contracted the ophthalmia. Dr. A. O. Bogert, who was in daily attendance, recognizing the peculiar features of the case, isolated it at once. I saw her twenty-four hours later and found a severe case of double diphtheritic conjunctivitis, the palpebral and ocular conjunctiva were infiltrated with, and covered by typical diphtheritic membrane. Central corneal necrosis had already commenced. The apparently hopeless nature of the case led me to disregard the rules against operative interference. Thoroughly cleansing the eyes with a saturated solution of boric acid, I performed canthotomy and paracentesis on both eyes. By means of a fountain syringe the conjunctival surfaces were now continuously irrigated for the next four days with the boric acid solution, the nurse everting the lids—a procedure rendered easy by the canthotomies—and playing a gentle stream incessantly into the eyes, alternating between them every three or four minutes. During the first twenty-four hours the fluid was used ice cold. At the end of this time the false membrane showed signs of separation, and had not extended to the canthotomy wounds; but as the corneal opacities were slightly increased, ice was discontinued in the solution and it was used at a temperature of about 100° F.

The following day showed a decided improvement, especially of the cornea, and from this time the favorable progress of the case was uninterrupted, the corneal infiltrations separating as superficial sloughs, leaving the

corneæ clear but astigmatic. The irrigation was practised incessantly for ninety-six hours and then with gradually diminished frequency until recovery.

Hourly doses of the tinctura ferri chloridi with a liberal supply of milk-punch were used throughout. No case of undoubted diphtheritic conjunctivitis has since fallen into my hands for treatment; but in membranous, gonorrheal, and purulent conjunctivitis I confidently look for a subsidence of the acute and dangerous stage under a few hours of continuous antiseptic irrigation. Corrosive sublimate, 1 to 20,000, may be used alternately with the boric acid solution for half an hour once or twice during the day, but its continual application produces an erythema of the skin and irritates the conjunctiva. As I use this method extensively in hospital work, I have devised drains to carry off the waste water and prevent wetting the patient.

CLINICAL NOTES ON FIVE CASES OF BERI-BERI.

By R. PERCY CRANDALL, M.D. U.S.N.,

U. S. NAVAL HOSPITAL, NEW YORK.

During December last there were admitted to this hospital, from the Brazilian cruiser Guanabara, then at anchor in the harbor, five cases with the diagnosis of beri beri. The medical officer of the ship stated that no evidence of the disease existed prior to their arrival in these waters, though it was probably latent, and had been developed by the intense cold, to which the men were entirely unaccustomed.

Aitken defines beri-beri as "a constitutional disease expressed in the first instance by anæmia, and subsequently in acute œdema. It is marked by stiffness in the limbs, numbness, and sometimes by paralysis of the lower extremities, oppressed breathing, and a swollen and bloated countenance. The urine is secreted in diminished quantity. The œdema is general, not only throughout the connective tissue of the muscles, but throughout the connective tissue of solid and visceral organs in every cavity of the body. Effusion of serum into the serous cavities very generally precedes death."

The disease is almost entirely unknown in this country, although very common in the tropics and throughout India, Japan, and China. Its territorial range is very limited. It is usually endemic and is principally met with on the Malabar coast, in Ceylon, and in that tract of country lying between Madras and Ganjam (Hamilton).

The clinical history of the cases sent from the Guanabara followed out very closely Aitken's definition of the disease. The cases so nearly resembled each other that they may be studied in one group. On admission, the most marked symptoms were dyspnœa and stiffness about the lower extremities. The pulse-rate ranged from 80 to 110. The temperature averaged 99° F., and respirations 30. There was entire absence of pulmonary involvement. The increased respiratory rate and dyspnœa were attributed to fluid in the pericardium, the area of cardiac dulness being increased. Irritable stomach was observed in each case. In two only did œdema of the feet develop. Examination of the blood revealed a diminution of the red blood corpuscles without increase of the white. In two cases the stiffness and anæsthesia of the lower extremities was very marked, amounting to almost a complete paralysis. Improvement under treatment was very rapid. Treatment consisted in small doses of arsenic, hydrarg. chlor. corros., massage, and galvanism. In one case very strong currents were necessary to produce movements in the thigh muscles, but daily applications soon restored them to their normal tone. The cases completely recovered, and have been sent back to Brazil.

The cases are interesting as having occurred so far north, and from the success of the treatment followed.

Progress of Medical Science.

Predisposition to Tuberculous Infection.—Professor Birch Hirschfeld, of Leipzig, comments on the question of predisposition to tuberculous infection, pointing out that the prevailing theory of direct infection by inoculation of the bacillus is rapidly coming to be regarded as the only important factor in the spread of the disease. Predisposition may be classed as "general" and "local," meaning by the first term a greater or less resistance to the development of tubercle; and by the second the various factors that incline an individual organ or part to become tuberculous. General predisposition may be inherited or acquired, as in the case of diabetes. Local predisposition may depend upon the condition of the local tissues, the opportunities which they afford for the entrance of the tuberculous virus, and the amount of resistance which they set up against its development. Inherited predisposition is strengthened by the fact that, up to the present time, the evidence of direct conveyance of the disease from mother to fœtus in utero has not been well established in the human species, although undoubted instances have been reported as occurring among certain animals. Dr. Birch-Hirschfeld relates a case in which a fœtus was removed from the uterus of a woman aged twenty three, within a few moments of her death from general tuberculosis, without any damage being done to the placenta. Portions of the liver, spleen, and kidney of the fœtus produced tuberculous disease when inoculated into rabbits and guinea-pigs, but only in the capillaries of the liver could any tubercle bacilli be discovered. In the placenta, however, the villous spaces were crowded with bacilli. The very limited evidence of tuberculous material in the fœtus might serve as an explanation of the fact that children of tuberculous parents are often born without any manifestations of tuberculous disease, and yet appear to develop tubercle during the first few years of life. A limited infection by the maternal bacilli, perhaps during the process of birth, might remain latent in one or more organs until other circumstances contribute to their development. It is thus possible that confusion may exist between "latent tubercle" and "tuberculous predisposition." That latent tubercle may remain quiescent, especially in bronchial glands, until awakened by an attack of acute disease, such as measles or whooping cough, is well known. The frequent occurrence of such latent tuberculous foci, without any other evidence of tuberculous disease, goes far to prove that resistance to tubercle is as powerful a factor as predisposition. The congestive influences of valvular disease of the heart and of emphysema upon the connective tissues of the lungs are examples of some of the mechanical causes which constitute resistance.—*Wiener Medizinische Blätter.*

Corpora Amylacea in the Lungs.—The occurrence of the objects known as "amyloid bodies" in the sputum is rare. Friedreich was the first to observe them, in 1856, and he ascribed their origin to the remains of old hemorrhages in the lungs. A very complete account of these interesting bodies is given by Dr. F. Curtis. He describes two cases in which corpora amylacea were found in the lungs. They presented a typical appearance, occurring as oval or circular grains, but when separated from the surrounding tissues by teasing they were found to be almost geometrically ellipsoidal in shape. The longest diameter was from 125 to 150 μ in the largest specimens, varying to 16 or 20 μ in the smallest. They were composed of a vitreous looking substance, stratified in irregular layers around a central nucleus, which differed in appearance from the peripheral layers, which were so arranged as to present a radiated formation. The central portion was sometimes scooped out so as to form a small hollow, from which shallow fissures extended, and sometimes was filled up with a material which was of a different composition to the rest of the

grain. In some of the bodies the nucleus was represented by a small granular mass; in others by a cylindrical one, folded upon itself. Some of the grains were enclosed in a thin crystalline envelope of a black color. In fact, all the varieties were found which had previously been described by Friedreich and Zahn. The chemical reactions were equally characteristic, and especially so in those specimens which had been preserved in Muller's fluid. A solution of iodine in iodide of potassium produced a deep blue color, and this tint became almost black on the addition of sulphuric acid. The nucleus was stained yellow by the iodine, a fact previously noted by Friedreich. Methyl-violet caused the same reaction as in amyloid disease generally, coloring the grains red, while the surrounding tissues assumed a blue tinge. Methyl-green failed to cause any special coloration. Picro carmine had a peculiarly selective action, staining the bodies a deep red. Lastly, methylene blue was tried and results obtained which have been noticed by no previous observers. The nuclei of cells were colored blue as usual, but the corpora amylacea assumed an emerald-green color. In amyloid disease of the liver, the tissue is stained blue throughout when similarly treated, the diseased portions only taking up the green color, when a drop of a solution of picrate of ammonia is added to the dye. As regards the pathological significance of these amyloid concretions, many diverse theories have been suggested, the two principal being those of Friedreich and Langhans. The former considered that these bodies were derived from hemorrhages in the lungs; in all his cases there was a history either of recent hemorrhagic infiltrations or traces of past inflammation. His theory was that a small clot formed locally, thus constituting the nucleus, and that fibrin was deposited in layers around it; that this formation underwent modifications, of what kind is at present unknown, which caused the bodies to assume their characteristic appearance and properties. Langhans, on the other hand, assigned to the corpora amylacea a cellular origin. In this he has but few supporters, and moreover the bodies described by him do not agree in all particulars with those now under consideration. The observations of Jurgens and Zahn corroborate those of Friedreich, and Dr. Curtis has arrived at similar conclusions from the cases which he has observed.—*The British Medical Journal.*

Changes in the Kidney in Phthisis.—The condition of the kidneys in phthisis has never been fully investigated. Several observers have described a fibroid condition. Becquerel and Rayher concluded that Bright's disease was very frequently associated with tubercular disease of the lungs. Peacock in 117 cases of kidney disease found 30.7 per cent. of phthisis. Frerichs found that out of 42 cases of Bright's disease 6 also suffered from phthisis. Bamberger stated that the disease was found in 15 per cent. of those suffering from kidney disease. Dr. C. von Kahlden is of opinion that slight degeneration of the renal epithelium is almost always found in active phthisis. It may, however, be so slightly marked that it is only visible on microscopic examination, and even then may be easily overlooked. The kidney may be either normal in size or somewhat enlarged. Microscopically the following conditions are noticed. The surface of the organ is smooth and yellowish in color; the capsule peels easily; the cortex is usually slightly thickened, and also yellow in color; the medullary portion is pale. The microscopic changes chiefly affect the cortex, the parenchyma being first attacked. The epithelial cells undergo fatty degeneration, but are occasionally replaced by fresh epithelial cells. The interstitial changes are therefore secondary, and generally slight, and take the form of a small round celled infiltration, and some increase of the connective tissue. The glomeruli also take part in the degeneration. The cortex is not uniformly affected, but the changes take place in patches. These lesions are evidently chronic, as is shown by the thickened capsule, the atrophy of some of the glomeruli, and the changes in shape of the epithelial cells of the tubules, these being altered from a club form to a cubical or cylindrical shape. Clinical symptoms which accompany the renal degeneration are unreliable. Albumin in the urine is rarely present. The author states that the condition is one of a chronic parenchymatous nephritis, and thinks that it may be caused by the poisonous products of the tubercle bacilli.—*The Lancet.*

Occlusion of Duodenum in a New-born Child.—Drs. Porák and Bernheim described a case where a woman was delivered at the eighth month of a sickly female child. There was hydramnios, and over six pints of fluid came away during labor. There were two small fibrous deposits in the placenta. On the first day the child vomited dark matter, each attack of vomiting coming on about three-quarters of an hour after suckling. On the third day, as no meconium had passed, imperforate rectum was suspected; but a sound could be passed for over two inches up the anus. An enema was given, and a little meconium came away; but the vomiting continued, and the infant died on the fifth day. The stomach was found much dilated; the lower part of the large intestine was full of meconium, but the remainder of the intestinal canal was like a little packet of worms. The stomach communicated by a contracted orifice, apparently the pylorus, with a blind pouch which had no connection of any kind with the rest of the intestine, which terminated above in a blind extremity close to the pancreas, which opened into it. In a similar case reported by Crooks in 1828, the pancreatic duct opened into the pouch connected with the stomach. Luton described in 1855 a third case, where that pouch communicated with the blind end of the intestine by a ligament. There was a similar breach of continuity between the large and small intestine. No trace of peritonitic bands could be seen in Drs. Porák and Bernheim's case.—*The British Medical Journal.*

The Abortive Treatment of Buboes.—Dr. Welander reports a second series of fifty-nine cases of bubo treated by means of injections of benzoate of mercury. In all, he has now treated one hundred buboes in this way with thoroughly satisfactory results in seventy-eight. He uses the following formula:

℞. Hydrargyri benzoatis..... gr. v.
Sodii chloridi..... gr. jss.
Aquæ destillata..... ʒj.
Sig.: ♏xv. as an injection.

As a result of his observations he has arrived at the following conclusions: 1. If the bubo display a virulent tendency the injection does not affect its development, and suppuration occurs. 2. When decided fluctuation exists and the skin is thin and cyanotic, the injection can only hasten the disappearance of the infiltration. As a rule, the bubo must be opened. 3. If fluctuation is considerable in degree, but the skin, though red, is thick and well nourished, the chances are good that an injection into the adjacent infiltrated area will (possibly in 50 per cent. of cases) obviate the necessity of opening the bubo. 4. If there is little or no fluctuation, it is highly probable (possibly in 90 per cent. of cases) that, even though fluctuation subsequently becomes decided and a few drops of pus ooze from the site of puncture, the bubo will disappear, leaving no trace of a cicatrix.—*Medical News*, September 19, 1891.

Fined for Saving Life.—In a small village in France a woman died in labor. There was no medical man present, but a priest was there, and he at once performed a Cæsarean section, bringing a living healthy child into the world. The priest was arrested and tried for the illegal practice of medicine, and the court imposed upon him a fine of 15 francs. The question of the justice of this sentence would make a good subject for a medico-legal debating society.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 10, 1891.

THE METHODS OF SECURING IMMUNITY AGAINST DISEASE.

No class of experiments is at present attracting or deserving more attention than those which relate to the securing immunity against infectious diseases. While success has been obtained experimentally in a few diseases, no fundamental principle has yet been discovered which can be applied to all diseases. Yet such a discovery seems not impossible, and Wooldridge's method of producing immunity against anthrax, by the injection of tissue fibrinogen, is of special interest because it tends in this direction. Dr. A. E. Wright (*British Medical Journal*, September 19, 1891) has recently confirmed Wooldridge's experiments and added to our knowledge of the chemistry of the injected substance. This is prepared, we are told, in the following way:

The perfectly fresh cellular organs (testicles, thymus, etc.; in the experiments to be reported the fluid was always prepared from bulls' testicles) are reduced to a pulp in a mincing machine, and are extracted for twelve hours with water to which, for antiseptic purposes, an addition of 1 in 200 of chloroform has been made. The watery extract is then either centrifugalized, or filtered, or simply decanted. It is then precipitated by the addition of 0.5 c.c. of thirty-three per cent. acetic acid to every 100 c.c. of the extract employed. The precipitate is collected and washed with NaCl solutions of moderate strengths, and lastly with distilled water. (All these washing fluids are rendered slightly acid by the addition of a trace of acetic acid.) The precipitate is now dissolved in a one per cent. solution of Na_2Co_3, and afterward filtered.

Dr. Wright offers evidence to show that the tissue fibrinogen is a nucleo-albumin. He promises to report the results of further experiments, giving more exactness to our knowledge of how immunity is obtained in the case of anthrax, at least.

Meanwhile experiments in other directions have been going on in German laboratories. Among the most interesting of these are the attempts of Drs. G. and F. Klemperer to secure immunity against pneumonia, and to antagonize and shorten the course of that disease. It is not generally known perhaps that, in animals at least, one attack of pneumonia causes a temporary immunity against another. The experiments of the Drs. Klemperer, which were confined to rabbits, revealed that every nutrient medium in which the pneumococcus has been cultivated will, if inoculated, render an animal immune against pneumonic septicæmia, even after the cocci have been removed by filtration. The power of producing immunity is more speedily acquired, and is increased, if the infected nutrient medium (before or after removal of the cocci) is exposed to a temperature of between 41° to 42° C. for two or three days, or of 60° for an hour or two. In every case, however, it was found necessary that some interval (varying from three to fourteen days) should elapse between the inoculation and the production of immunity. Hence it was too late to cure a diseased animal, or even to prevent the onset of an attack, if the injection was given simultaneously with the outbreak of the disease. On the other hand, serum taken from animals enjoying immunity was found able, especially when introduced directly into the circulation, to cure pneumonic septicæmia. The serum was injected twenty-four hours after infection, while the animals had a febrile temperature of between 105° and 106.5° F. Eight cubic centimetres were injected, with the result that the temperature gradually sank during the next twenty-four hours. In twelve successive cases a successful result was obtained. This research therefore confirms, in regard to pneumonia in rabbits, what Behring and Kitasato did for tetanus and diphtheria. Drs. Klemperer next studied the question how the blood-serum of an immune animal cures an attack of pneumonic septicæmia, and discovered that when the pneumococcus is introduced into the body of an animal it generates a poisonous substance which can be isolated, and to which the name of "pneumotoxin" has been given. This pneumotoxin sets up a febrile condition which lasts several days, after which another substance is found to have been produced, called "antipneumotoxin," which is able to neutralize the pneumotoxin. The serum taken from an immune animal contains this antipneumotoxin, and it is by means of this substance that it cures an attack of pneumonic septicæmia in other animals. The relation of pneumonia as seen in rabbits with that met with in man was next investigated, and the conclusion arrived at that the disease in both cases is produced by the pneumococcus, but that the human body is much less susceptible to the latter than the rabbit is. Thus it was found that serum taken from pneumonic patients after the crisis could cure pneumonia in rabbits; moreover, pneumotoxin and antipneumotoxin were found to be present in human serum as in that taken from rabbits. The crisis of pneumonia, according to Drs. Klemperer, takes place as soon as antipneumotoxin is produced in sufficient quantity to neutralize the pneumotoxin. Why immunity against further attacks lasts so short a time in man is still uncertain, but possibly less antipneumotoxin is formed in man than in rabbits in proportion to the pneumotoxin. Some attempts, according to the *British Medical Journal*, have already been made to cure patients suffering from pneumonia with the help of antipneumotoxin, but further observations are necessary before results can be published.

If we were not suffering from the depression following the tuberculin failure, the imagination might easily be fired by the therapeutic possibilities of an antipneumotoxin. As it is, we can only hope for its success.

SIMPLE ADENIA, OR HODGKIN'S DISEASE.

Every year there are reported in medical literature three or four cases of Hodgkin's disease, or lymphadenoma. The most of these reports have been simply clinical records, and have not thrown much light upon this confessedly obscure disorder. We cannot say very much more regarding an elaborate thesis on adenia, or pseudo-leukæmia, by Dr. Jean Crocq fils, of Brussels. Still Dr. Crocq has made a most industrious collection of the previous literature of this subject, and has edited his records with much intelligence. His monograph is, therefore, a very useful one.

Out of the numberless and confusing names supplied for Hodgkin's disease, Crocq has selected Trousseau's term "adenia" as most satisfactory. If he would go a little further and distinguish between simple adenia (pseudo-leukæmia) and leukæmic adenia (leukæmia, leukocythæmia), as suggested by Langhans, there would be much less confusion in this very name-ridden subject.

Dr. Crocq collects one hundred and twenty-one reported cases of supposed Hodgkin's disease, with autopsies. But after an analysis of them he throws out all but fifty-four, which shows that there have been many careless observations or incomplete records. A clinical study of these fifty-four cases furnishes some interesting facts.

In forty six cases the disease occurred in men, so that it is about eight times as frequent in the male sex.

Simple adenia occurs oftenest between the ages of twenty and thirty, then again it is frequent between fifty and sixty. Leukæmic adenia is most frequent between the ages of thirty and forty.

Leukæmic adenia (leucocythæmia), it has been suggested, is an infective disorder (Klebs). Simple adenia is thought, however, to be due to local irritation acting upon a predisposed constitution. In other words, it is placed etiologically in the same category as the cancers, to which in its malignant course it bears resemblance. The disease is not caused by malaria, nor does it have any relation to tuberculosis.

The symptoms of the disease, as detailed by Dr. Crocq, present nothing new. The pathognomonic sign of it which distinguishes it from leukæmic adenia is the fact that there is not an increase in the white blood-cells.

The prognosis is always fatal, and usually rapidly so.

The treatment recommended by one author is purely palliative. He recommends the use of the iodides, and yet says that they do no good. He lays less stress, we believe, than should be done on the value of arsenic.

The monograph from which we have quoted shows in a very bold and striking way that there are still diseases of whose intimate nature and origin we know nothing, and before which the physician stands perfectly helpless. In the *lingua vulgaris*, Hodgkin's disease beats the doctors "hands down."

A WONDERFUL SURGICAL OPERATION.

It sometimes seems as if, after all, it is only by careful perusal of secular literature that one can learn what is going on in the scientific world. In one of the monthly magazines there has recently appeared a description of "a wonderful surgical operation." It differs from many of the ordinary descriptions of this class in that the operation was really wonderful. For the surgeon did a double linear craniectomy with a transverse cut and two lateral cuts going down toward the ears. The child, one year of age, was apparently a microcephalic idiot before the operation, but one month later it acted and thought like other children. It was transformed into macrocephalic prodigy!

Such stories, written by persons of enthusiastic temperament and ill-balanced minds, are likely to do harm. For the operation in question is rarely indicated, is very dangerous, and is yet of doubtful utility.

ARE GEORGIA PHYSICIANS INTEMPERATE?

This question is suggested by the fact that the State Legislature of Georgia is said, by the *Sun*, to have passed a law to prevent drunkenness among physicians.

The Georgia statute disqualifies any medical man from further practice who has once been convicted of drunkenness, and imposes a heavy penalty upon the man thus disqualified if he attempts to practise medicine again.

In New York we have a law on the subject. It does not deal with drunkenness on the part of doctors except when they are engaged in the treatment of patients, and then it provides for punishment only when the intoxication has resulted in some actual injury to the patient. Our statute is contained in section 357 of the Penal Code:

"A physician or surgeon, or person practising as such, who, being in a state of intoxication, administers any poison, drug, or medicine, or does any other act as a physician or surgeon to another person, by which the life of the latter is endangered, or his health seriously affected, is guilty of a misdemeanor."

Another section of the same Code declares that like acts committed by an intoxicated physician, causing the death of his patient, shall constitute manslaughter.

The Georgia law is an insult to the profession of the State, because its existence implies a serious and preponderant degree of intemperance among medical men. It is in addition a form of special and class legislation of the worst character. Under it, a doctor who has led a sober and useful life for a long time may, as the result of a single indiscretion, have his career ruined and his means of subsistence taken away. But the lawyer or editor or farmer can stay drunk for a year with relative impunity. If such a statute, therefore, really exists, the physicians of Georgia should see to it that it is repealed, or be convicted of possessing neither manhood nor self-respect.

THE TWO TYPES OF AORTIC INSUFFICIENCY.

In a critical review of the subject of aortic insufficiency by Dr. Easton Lyon (*Gazette des Hôpitaux*, June 13, 1891), stress is laid upon the fact that there are two rather distinct types of this disorder which ought to be recognized. These are the endocardiac type and the aortic type. The former affects especially young subjects, it most often follows rheumatism, it may remain stationary for years, and it is before all an affection of the heart. The latter affects older subjects, it is related to arterial sclerosis, and is especially a disease of the arteries. While

these two types may not always be distinct, and may even run together, yet the pathological and clinical difference is a distinct and real one.

Taking up the subject of the endocardiac form, Dr. Lyon goes over, first, the question of its etiology. Here the two great factors are trauma and infection, the infection being usually rheumatic fever.

Rheumatism, according to the French statistics, affects the heart's valves in about one-third of all cases, and in about one-third of these the aortic valves are attacked. The infection of typhoid, scarlatina, and erysipelas sometimes acts similarly. Trauma is a rare cause. Three-quarters of the cases are males and most of these are adults. The lesions of the valves are those due to acute and to chronic endocarditis. Under the former head we have ulcerations, vegetations, and valvular aneurisms; under the latter a reticulated condition, rupture, and valvular aneurism. The aorta is healthy, but the heart is dilated and hypertrophied.

It is not necessary to go into the detailed analysis of the symptoms as given by Dr. Lyon, since they are familiar to all. The capillary pulse, the tonsillar pulse, and the retinal and pharyngeal pulsations, are curious and striking symptoms sometimes observed in this type.

Aortic insufficiency of cardiac origin is thought to be the form of heart disease most compatible with long life, provided the patient has no other valves involved, and does not have to lead a laborious life. Cures have even been claimed by Potain and others. Sudden death is rare, though perhaps more frequent than in mitral disease. It may be due either to embolism or heart failure.

In the matter of treatment, Dr. Lyon asserts that digitalis is absolutely contra indicated, and that iodide of potassium does no good. Hygienic measures and opium are the only things recommended, and if this represents the limits of French therapy one must consider it rather barren.

Aortic insufficiency of the arterial type is really but one manifestation of a generalized arterial sclerosis. It is caused by the infectious, toxic agents, and diathetic poisons; hereditary influence is also a factor. The valves are indurated and sclerosed, the orifice dilated, the heart hypertrophied. The aorta is always dilated, and incrusted with atheromatous plaques. There is excessive arterial tension, increase of dulness at the base of the heart, a double murmur, and often local pain on percussion. The subjective symptoms are much more varied and severe than is the case in the cardiac form: anginal attacks, vertigo, syncope, dyspnœa, palpitations. Death more often occurs suddenly from heart failure, cerebral hemorrhage, or from uræmia.

The treatment here recommended is iodide of potassium, trinitrine, caffeine, milk diet, and intestinal antisepsis.

THE PATHOLOGY OF THE JEWS.

Many persons have at different times occupied themselves with contributing various facts and theories regarding the relation to disease of the Jewish race. We have occasionally been told that the Hebrew is less subject to cancer or syphilis, and is perhaps more subject to diabetes and neuroses, than other persons. This matter was discussed with an interesting candor before the Académie de Médecine quite recently. M. Worms took up the subject of epilepsy, and apparently proved by statistics that this disease was not relatively frequent among Hebrews. Among 25,000 Jewish patients, for example, there were found only 77 cases of epilepsy. In Salpêtrière and Bicêtre the number of Jewish cases was also small. M. Worms, however, agrees with Charcot in thinking that his race is rather specially disposed to neurasthenia, hysteria, tabes, gout, and diabetes.

MM. Lagneau and Bouchardat thought that the Jews were especially prone to "music and mental alienation." M. Lagneau also quoted the statistics of Frerichs and Seegen, to the effect that about twenty-five per cent. of their diabetic patients were Jews. M. Sée takes up the cudgels for the Hebrew race, and asserts that the statistics quoted are of doubtful value, and that if any tendency toward nervous and diathetic diseases exists, it was due not to ethnic causes, but simply to the urban life and commercial pursuits of the Jews. There is, says M. Sée, no pathology of the Jews, and the subject is consequently outside the pale of scientific discussion.

HOSPITAL AND DISPENSARY QUARRELS.

Our German colleagues of this city seem to have an unfortunate tendency to develop controversies in connection with their medical charities. The German Hospital trouble being, we believe, settled, reports are now abroad of an enormous disturbance in the dispensary of Beth Israel Hospital. The main trouble seems to have grown out of attempts of the lay managers to exercise authority too arbitrarily, whereupon the physicians protested and resigned. It is a satisfaction to know that, so far as the published facts indicate, the physicians here as in the German Hospital case, are in the right. But the disturbance emphasizes anew the fact that in the management of hospitals and dispensaries, there should be closer relations and the utmost harmony between the medical and the governing boards. While most members of medical boards are either too busy or too indifferent to take much interest in the debates of hospital or dispensary management, there are always some who have practical wisdom and business capacity. Possessing such qualities, and with the additional advantage of medical knowledge, their advice becomes of greatest value. Yet we regret to say that in a good many of the medical charities of the city, the attitude of medical and governing boards is almost an antagonistic one.

Music and Therapeutics.—It has lately been suggested that music might prove a useful adjunct (in some cases at least) where the usual routine treatment had not been satisfactory. We venture to suggest the following airs as being suitable for the cases enumerated, viz.: Retarded labor from inertia, "Comin' Thro' the Rye;" cases of chronic deafness, "Come Back to Erin;" epilepsy, "Let Me Like a Soldier Fall;" pyrexia, "The Coolin;" melancholia, "The Heart Bowed Down;" cases of doubtful diagnosis, "Oh, Dear! What Can the Matter Be?"—*Medical Press*

News for Bald Heads.—Dr. Mapother finds that a diet of oatmeal and brown bread greatly promotes the growth of hair.

News of the Week.

Suing Physicians for not Reporting Contagious Diseases.—Health Commissioner Ware, of Chicago, had suits instituted against a number of physicians for failing to report to the Health Office cases of contagious diseases. The law requires an immediate report of all contagious diseases under a penalty of a fine of $100. We trust that the suits will be brought to trial and the constitutionality of the law compelling physicians to give their time and experience to the State for nothing tested.

A New and Volatile Antiseptic for the Treatment of Phthisis.—This is another effort directed to destroy the tubercular microbe which Dr. Passerini has proved to be a success! The same experimenter has long endeavored to modify the trichlorphenol, but the odor and irritation to the mucous membrane is always a serious objection to its use. Dr. Tacchini, of Pavia, has now obtained a preparation of chlorphenol which has as much antiseptic power as trichlorphenol, and is free of all the objections against the latter. Chlorphenol is a very volatile fluid, whose vapor is heavier than air. When applied to wounds, ulcers, and discharging glands the improvement is marked. Ozæna, laryngitis, bronchitis, and more particularly tubercular affections, are beneficially affected. Passerini has treated five of the latter cases with the vapor, which being heavier than air, presumably reaches the bronchioles, if not the alveoli, of the lung itself, and he finds that the bacilli rapidly disappear after commencing the inhalations. All the five cases have quite recovered, varying from two to six months from beginning of the treatment, and are apparently well at the present time. The claims put forth are: 1. The inhalation of chlorphenol is easily borne in advanced phthisis, and is convenient in application. 2. No injurious effects arise from its continuous use. 3. Changes in the quality and quantity of expectoration till pus and bacilli disappear; cough is diminished; fever is reduced; appetite and sleep soon return; the weight of the body increases rapidly, and the local improvement is speedily performed. Hence the three conditions, applicability, innocuity, and efficacy are the dominant recommendations of the drug.—*Medical Press.*

The Successor to Professor Carl Braun has been elected in the person of Dr. Friedrich Schauta, of the University of Prague, the author of a "Manual of Operative Midwifery" and numerous lesser works. He will occupy the chair of midwifery and conduct the first obstetrical and gynecological clinique.

A New Remedy for Whooping-cough is onabaine in doses of about gr. $\frac{1}{1000}$. It has been tried with success by Dr. Gemmell, of Glasgow, and lately by Dr. I. L. Porteous, of Yonkers, N. Y.—*New York Medical Journal.*

A New Disease called Germosphism has been described by Drs. Charcot and Souques (*New York Medical Journal*). The word means age-like, and the disease produces an appearance of senility. The case reported was that of a woman whose age was twenty-one, but whose physiognomy was that of sixty to seventy years. Her apparent senility was so striking that her father, aged fifty-two, had occasionally been asked if she was not his mother. The pathology of the case is limited to the skin, especially on the surface, and is a "decrepitude of the cutaneous system." Otherwise the girl had nothing old appearing about her. Her hair was blonde and of average length. Her intelligence was good, her memory precise, and her judgment reasonable, but she was readily frightened when in a crowd, or by a railroad and its noises; her emotional nature was fairly well balanced, but she was despondent on account of her appearance of age, which she had come to believe was incurable, and the slightest indisposition begot a fear of death. Her cutaneous sensibility was normal. The special senses of smell, taste, and hearing were normal. There was a slight impairment of vision, without contraction of the visual field or color-blindness; there was no arcus senilis. The hepatic, renal, and uterine functions appeared to be normally performed; a slight leucorrhœa had existed for two years. The wrinkling had begun about ten years before, at which time she received a great fright. She was then a bright, joyous child, very pretty and refined in her appearance, and always in the lead of her classes at school. When the change in the skin began, there was, for a short time, the formation of pimples, which persisted a few days and then disappeared without ulceration or mark of any kind. There was no œdema of the cutaneous surface. The wrinkling changes took place so rapidly that, it is stated, her friends were unable to recognize her if they had not seen her within the period of a fortnight; the skin at that time is described as resembling "the scales of a fish." No form of treatment, whether by electricity, hydropathy, or tonics, has been competent to improve her condition.

The Medical Department of the University of Texas starts out with a full line of new professors, whose official salaries range from $2,500 to $3,000.

A Buddhist Treatise on Medicine.—All those interested in the history of medicine, and particularly Indian medicine, will hail with scholarly delight, says the *British Medical Journal*, the announcement that an old Sanscrit treatise on the healing art has recently come to light under somewhat remarkable circumstances. The "find" is in itself hardly of such value as the work of Aristotle not long ago exhumed from the grave of oblivion in which it had lain so long entombed; but your true Dryasdust cares little for the literary or scientific quality of his treasure trove, if it but have the consecrating seal of hoary antiquity upon it. Last year, it will be remembered, Lieutenant Bower was fortunate enough, in the course of an exploring expedition in Kashgaria, to light upon a buried city in the neighborhood of Kuchar. Among the other antiquarian treasures found there was an ancient birch-bark manuscript, which was presented to the Asiatic Society of Bengal. The manuscript, which consists of thirty three leaves closely written over on both sides, is in Sanscrit verse, and in the character known as the Nagari alphabet, of which three varieties occur in different parts of the work. The manuscript has been translated by Dr. Rudolph Hoernle, and appears to be a compendium of medicine, bearing the title of "Navanitaka," and divided into sixteen chapters. The author seems to have been a Buddhist, but, with a

modesty not always found among medical writers. he has concealed his name so carefully that Dr. Hoernle has not, up to the present, succeeded in discovering it. The work is divided into sixteen chapters, which are devoted to clysters, elixirs, eye-washes, hair-dyes, bitumen, castor oil, women and children, etc. The prescriptions, which are given in verse, recalling to the profane mind the gnomic scraps of clinical and therapeutic lore quoted by Albert Smith in his "Physiology of the Medical Student," celebrate the wondrous effects of clarified butter, which our Buddhist brother seems to have considered the "sovran'st thing on earth" for all manner of bodily ailments. A draught containing this panacea, together with oil, treacle, vinegar, and ginger, will, we are assured, instantly conjure away the most acute lumbago. An ointment composed of thickened goat's milk and wheat flour, to which sesamum may with advantage be added, is a specific for gout and rheumatism. In addition to the pharmacological and therapeutic precepts which the work contains, the reader has, it need hardly be said, a goodly *armamentarium* of charms and spells of approved efficacy supplied to him, so that if medicine fails, recourse may be had to the "faith cure." The date of the manuscript is fixed by Dr. Hoernle between 450 and 550 A.D. It is thus, so far as is known, the oldest Indian written book in existence.

Electrical Executions.—The report of the two physicians who had official charge of the electrical executions at Sing Sing, on July 7th, shows that the application of the current in the four cases was made somewhat experimental. In the first case the current of 1,485 volts was applied for twenty-seven seconds, and, signs of life appearing, was applied again, after an interval of between one and two minutes, for twenty-six and a quarter seconds. In the next case, to ascertain whether continuance of the current, or the sudden impact of and breaking it, was more important, three contacts of ten seconds each were made, and then, signs of life appearing, a contact of nineteen seconds was made, when life was extinct. This showed that continuance of the current was important. In the third case three contacts of the current, of twenty seconds each, were made. The result indicated that they were unnecessarily long, and in the last case there were three contacts of fifteen seconds each, with intervals between them of twenty seconds. And yet we were told, before the tardy official report was published, that electrical execution was a triumphant success!

Rupture of the Stomach from the Use of the Stomach-pump.—Dr. Key Aberg publishes in a Scandinavian medical journal an account of a case in which the stomach of a patient seemed to have been ruptured from the use of a stomach-pump. The patient was a man who had taken fifteen grains of opium with the object of committing suicide, and who had not been brought to hospital until three hours had elapsed. Under these circumstances the stomach was washed out somewhat hastily several times; each time it was remarked that only a portion of the water that had been injected returned. The patient died three hours after admission. At the necropsy it was found that the small curvature of the stomach had sustained several longitudinal ruptures, which, however, were confined to the mucous coat. The author was induced by this observation to make some experiments on dead bodies, which showed that an injection of three or four quarts of water into the stomach, under a pressure of about ten inches of water, produced similar injuries, and that these gradually increased, and ultimately became complete ruptures through the whole of the coats of the organ.—*Lancet.*

The Italian Medical Congress meets in Rome on October 19th, 20th and 21st.

The Woman's Medical College of the New York Infirmary has received a bequest of $5,000, for the benefit of its library, from the late Miss Sarah Hitchcock.

Physical Examination in a Bath.—The physical examination of patients, the subjects of disease of the abdominal organs, while in a bath, is advocated by Dr. Chapowski as greatly facilitating the exploration of these organs in doubtful cases. The advantages he claims for this method are: 1, That the tension of the abdominal muscles is reduced to almost nothing; 2, the patient is able to change from one position to another much more easily; and 3, that where the abdomen is extremely painful to the touch the pain is greatly lessened. The author practises this mode of examination in cases of movable kidney, tumors of or around the spleen, different abdominal growths, exploration of the rectum, etc., and recommends its adoption in cases where from any cause the ordinary method is unsatisfactory from a diagnostic point of view, as likely to lend considerable aid in arriving at a correct diagnosis.

The American Public Health Association will meet at Kansas City, October 20th, 21st, 22d, and 23d. Representatives from the entire United States are expected to be present, and from the treasure-houses of observations and investigations accumulated during the past year, contribute to the interest and profit of the occasion.

The Surgical Treatment of Obesity. — Last month Drs. Demars and Marx successfully began the surgical treatment of a patient affected with obesity. All drugs had been tried in vain, and the man had such an accumulation of fat over his abdomen that it formed a fold, hanging down and covering his thighs like an apron. Not only was walking greatly impeded, but painful erythema and intertrigo had developed to a dangerous extent. The surgeons made on the abdomen two horizontal incisions, one over the pubis and the other two inches below the navel; the two incisions were about nineteen inches long and six inches apart near the median line, and met at an acute angle on either of the patient's sides. The operators thus removed, adhering to the skin, a strip of fatty tissue, nearly five inches thick, weighing four pounds and a half. The wound healed rapidly and the improvement was marked.—Cor. *Therapeutic Gazette.*

Sterility in Woman.—Dr. Mary A. D. Jones writes: "Please allow a few corrections as to dates in the article on sterility that appeared in the MEDICAL RECORD for September 19th. The mistakes were made by my typewriter, and I, unfortunately, overlooked them. P. 323, first column, 'In 1890 Mrs. M——,' etc., should be 1882; p. 323, second column, 'In 1882 I restored,' etc., should be 1883; p. 324, second column, 'In 1865,' etc., should read 1876."

Society Reports.

THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Fourth Annual Meeting, held at the Hall of the Academy of Medicine, New York, September 17, 18, and 19, 1891.

The Association was called to order by The President, Dr. Adam Henry Wright, of Toronto, who, during some brief remarks, expressed confidence in the continued success of the Association.

The Address of Welcome was made, in the absence of Dr. Roosa, by Dr. Robert T. Morris, and was responded to by Dr. G. H. Rohé, of Baltimore.

Removal of the Kidney for Disease, with Cases.—Dr. William J. Asdale, of Pittsburg, reported three cases of removal of the kidney. The first case was one of sarcomatous degeneration of the kidney, the nature of which could only be suspected for some months, nor determined even until the operation, although a tumor as large as a cocoa-nut could be made out on palpation, which was believed to be malignant. The chief early symptom was hemorrhage, shown by blood in the urine. Pain was absent. The lateral abdominal incision was made, but the operation was undertaken too late, secondary deposits had already taken place; the patient died on the twenty-first day. The case showed the importance of an early diagnosis and the probable futility of a late operation.

The second case suggested two queries: 1. Was fatal uræmia hastened and made certain by surgical interference during a septic condition? 2. Would the use of another anæsthetic (ether was used) have been followed by a different result?

The case was one of pyonephrosis, the patient coming under observation after marked sepsis had developed. The pus-sac, which included the *débris* of the right kidney, was removed and drainage established; the patient rallied; but little urine was subsequently excreted, and the patient died within fifty hours.

The third case was also one of pyonephrosis, in this case a mulberry stone being found in the pelvis of the highly diseased kidney. In this instance hemorrhage took place from the renal vein, and was one cause of death.

Discussion of the paper was postponed until after the reading of one by Dr. R. T. Morris, of New York, on

Another Method of Palpation of the Kidney.—In the ordinary methods of palpating the kidney the mesentery and intestines were in the way. Israel's method, assisted by that of Gihon, enabled one to successfully make out the normal kidney in ordinary cases. In two or three cases in which the author had felt sure there was a movable kidney these two methods had failed to reveal it. It was in these cases that the advantages of a new method were shown. The patient, if the right kidney were to be examined, should lay upon the left side, the knees flexed upon the left in such a way that the abdominal contents sank toward the table. Thus a deep concavity was formed at the quadratus lumborum muscle. At this point the right kidney would be felt as the highest solid body resting in the abdominal cavity. In the other methods referred to, the colon and other structures intervened between the hand and kidney.

The participants in the discussion on these two papers were Drs. Vander Veer, Reed, Montgomery, Ross, Kellog, Carstens, and others. Those who expressed an opinion on a choice between ether and chloroform in operations on the kidneys gave the preference to the latter. They emphasized the importance of operating early where there was malignant disease, and regarding danger of hemorrhage from the renal vein.

Dr. Reed advised ligating the structures in which it lay *en masse*. Some of the gentlemen had had occasion to practise the methods of palpating the kidney described by Dr. Morris, and had found it a valuable one.

Dr. Kellog had found, where he had been unable to palpate the kidney with the patient in the prone position, that the organ could usually be felt while she stood stooping forward, with the arms resting on a table. In this position the abdominal muscles relaxed, and the contents, including kidneys, descended, and could be readily palpated, especially on deep inspiration. He had found, in examination of over six hundred persons, descent of one or both kidneys in a large proportion. Some descent of the kidneys, and also of the abdominal organs in general, was apt to be present in cases of descent of the pelvic organs.

Intra-uterine Irrigation after Labor.—Dr. Lewis S. McMurtry, of Louisville, read the paper. He said his object was not to point out the method of making intra-uterine injections, nor to show their value in prophylaxis. The paper was a plea for the use of intra-uterine irrigation in the very early stage of sepsis, before the system had become saturated.

The golden moment when the injections might be most efficient was lost while administering hypodermic injections of morphine, under the idea that the woman was suffering from milk fever or puerperal malaria.

The views expressed in the paper were accepted and emphasized by Drs. Potter, Montgomery, Rohé, Kellog, Carson, Cushing, Wright, and Ross.

Drs. Carson, Cushing, and some others, referred to a class of cases in which intra-uterine irrigations must fail. They included some of rupture of a pus-tube during labor. Here, other means failing to control sepsis, laparotomy should be performed to discover the real origin of the trouble.

Is a Child Viable at Six and a Half Months?—Dr. Llewellyn Eliot, of Washington, gave the history in this paper of three cases of premature birth with viability of the children. From the date of the last menstruation to that of delivery the time in one case was six months and eleven days, in another, seven months and one day, in the third case, seven months and sixteen days. The last one died on the fourth day, the other two were still living.

From these cases and some others in literature which he briefly analyzed, the author drew the following conclusions: 1, The child, under peculiar circumstances of development, is viable at four months; 2, a child is viable at six and a half months; 3, the moral character of the parents has nothing to do with the birth of a premature child when considered from the stand-point of constitutional development; 4, obstetricians should strive to convince the laity of these facts.

Dr. Marcy thought to him belonged the credit of saving the first child at about the sixth month in an incubator. The boy was then aged six or seven, and healthy.

Dr. Carstens thought the age of a prematurely born child could only be guessed at. It could be stated positively only when two facts were known, namely, 1, the date of last menstruation; 2, only one connection subsequently.

The Application of Sacral Section as Applied to Gynecological Work.—Dr. E. E. Montgomery, of Philadelphia, read a paper on the advantages of section of the sacrum according to Krasky's method in gynecological work. He had resorted to it in two cases. In one of malignant disease of the rectum and uterus the rectum was resected and the uterus removed through the free opening made by section of the sacrum. The patient had been much relieved of her symptoms and was still living. In the other case the section of the rectum was made to give room for removal of a large uterus and diseased tubes and ovaries. This patient also recovered.

Resection of the bone made convalescence more tedious than where simple vaginal hysterectomy was performed, but the advantage gained by having a freer passage for the operation more than compensated for this

objection. The operation had not been performed often enough to determine the exact amount of danger which attended it. He recommended resort to section of the sacrum in gynecological practice only where the vagina did not afford room for removal of the pelvic tumor.

Dr. Reed, of Cincinnati, was inclined to think that where removal of the cancerous uterus was indicated, it could best be done by one of the established methods, without adding the dangers of section of the sacrum. Possibly colotomy would have answered in the case of cancer of the rectum, yet he thought the operation performed by the author would deserve encouragement should it give relief, insure voluntary control, and not enhance the mortality.

Dr. Marcy thought it advisable to perform preliminary colotomy in order to empty the gut of gaseous and fecal accumulations.

Dr. H. T. Hanks thought there were few conditions in which free enough access could not be gained by way of the vagina or laparotomy.

Drs. Wathen, Vander Veer, and Vance spoke somewhat conservatively of the procedure, at least aside from resection of the rectum for cancer.

How Shall We Proceed when Abdominal Tumors are Complicated by Pregnancy?—Dr. James F. W. Ross, of Toronto, read the paper. It took into consideration only cases in which pregnancy had been recognized, and only cases in which the tumor was ovarian or myomatous. About the only paper on the same subject yet published was one by Dr. Vander Veer. The author cited some cases of ovarian tumor in which one had to choose between the following modes of treatment: 1, Allow pregnancy to go to term, or until the products of conception were thrown off; 2, puncture the cyst from time to time until delivery; 3, do ovariotomy, leaving the pregnancy to go on or to abort; 4, induce premature labor; 5, remove uterus as well as tubes; 6, do Cæsarean section, and remove the tumor at the same time or subsequently.

Tapping had been practised with safety a number of times, but was not applicable in multilocular or colloid cysts. Where it was thought best to remove the tumor, and its nature made likely the necessity for much handling of the uterus or rendered its puncture liable, he would first produce abortion.

Abdominal hysterectomy should be resorted to only where Cæsarean section was inadmissible on the ground of danger of hemorrhage, etc.

Should urgent symptoms arise, an operation should be done without delay. In myomatous tumors the indications might be, 1, to induce premature labor; 2, do early myotomy or abdominal hysterectomy; 3, late abdominal hysterectomy or Cæsarean section; 4, tentative measures, such as pushing the tumor out of the way during labor, etc.

In one case of repeated abortions from uterine fibroids, the husband refusing to take measures against conception, he was obliged to remove the appendages. Where practical, the tumor should be removed through the vagina.

Craniotomy, version, and forceps should give way to modern Cæsarean section or abdominal hysterectomy, in cases of labor complicated by fibroid tumors of the uterus. Cæsarean section should only displace abdominal hysterectomy in cases in which the latter could not be carried out, owing to the intra-pelvic character of the growth.

Dr. Hanks thought there was no necessity for acting in haste with regard to fibroids complicating pregnancy. In cases of cysts in hospitals, the choice might be in favor of an operation, but he would dislike to remove a unilocular cyst in the country and leave the case in the hands of the local physician. It would be safer to tap.

Drs. Cameron, of Toronto, Vander Veer, Marcy, and Cushing, pointed out the dangers of puncturing ovarian cysts. The paper was discussed also by Drs. McMurtry, O'Brien, Carstens, and the author.

Removal of the Uterine Appendages, with Results.—Dr. Milo B. Ward, of Topeka, Kan., related his experience with removal of the uterine appendages in a part of the country where there was generally opposition to the procedure. This scepticism regarding the value of gynecological surgery in this direction, and fear of unsexing the woman, manifest more at present in the West than in the East, accounted for the fact that the operation in many instances was permitted only late in the course of the disease, and did not in every instance save life. It was principally with a view to counteract this prejudice among physicians, who were the cause also of its spread among the laity, that he put his experience on record.

Dr. Joseph Price, of Philadelphia, in discussing the paper, gave a warm condemnation of "gynecological tinkering" in that class of cases pointing plainly to the presence of pus in the pelvic cavity. The teaching that one should not operate until all other means had been exhausted was in a certain class of cases altogether wrong. As great an authority as Mr. Tait had repeated this advice, although he knew Mr. Tait wisely failed to follow his own advice in this respect.

This view expressed by Dr. Price was also that of Drs. Cushing, Mordecai, Price, and Reed. It was admitted, however, that the surgeon sometimes allowed his fears to overcome his judgment, and that to convince patient and friends of the necessity of an operation required previous self-conviction of that necessity.

A Consideration of Emmet's Last Operation for So-called Laceration of the Perineum, or Prolapsus of the Posterior Wall of the Vagina, or Loss of Fascial Support, or Muscular Relaxation from Tears.—Dr. Joseph Price, of Philadelphia, read this paper, which was intended to demonstrate the value and technique of Emmet's last operation, and the explanation which it offered of the lesion present.

The need of such a paper was made evident by the fact that few who had not seen Emmet operate could practise the operation or understood the description of it contained in Emmet's writings. In over six hundred cases the author had had no failures with this method so far as healing was concerned, or other untoward symptoms, and in few could it be recognized that any operation had been performed were it not for two or three outside stitches.

The various flap operations could not be compared with it, and from an anatomical stand-point certainly they would not withstand critical examination. The author impressed the importance of passing the sutures deeply. This was true of primary operations also. Puckering operations were worthless.

Drs. Wathen, of Louisville, and Ross, of Toronto, favored the splitting operation; while Drs. Hanks, Mordecai, Price, and the author adhered to Emmet's.

The Prevention of Secondary Peritoneal Adhesions by an Aristol Film.—Dr. Robert T. Morris, of New York, thought he had been able to demonstrate the efficiency of an aristol film in preventing secondary peritoneal adhesions by experiments on rabbits, and also by its use in one case of laparotomy on the human subject.

Annual Address of the President.—Dr. Adam H. Wright, in his address, dwelt chiefly on matters concerning the welfare of the Association. He reviewed the correspondence which had taken place between the officers of the Association and the Executive Committee of the Congress of American Physicians and Surgeons regarding admission into that body, and deprecated the unfair and undignified action of that committee, which he believed would not have met with the approval of the individual members of the Congress. It looked somewhat as though there was danger of an aristocracy in medicine arising in America worse than the worst form of aristocracy existing in Europe. He pointed to the British Medical Association as an ideal body, representing the most distinguished as well as the humblest in the

profession. It was desirable that the specialist should come in contact with the general practitioner, with the great body of medical men throughout the country, and this he thought could best be done in connection with the American Medical Association and the sister association in Canada.

A Case of Cholecystotomy and Cholelithotrity; Death from La Grippe on the Twenty-first Day.—Dr. William Wotkyns Seymour, of Troy, read the paper, giving the history of one case in detail, referring to another, and explaining his choice of cholecystotomy and sewing the gall-bladder to the parietes, leaving an open fistula. In his case, notwithstanding the patient contracted la grippe and got up a severe cough, the sutures held, no leakage took place into the abdominal cavity, there was no ecchymosis. Death was due entirely to la grippe with pulmonary complications. If it could be shown that the gall-stones could in some way be dissolved, sewing the gall bladder to the abdominal parietes might properly be resorted to as an intermediate step, but as yet he had found no successful dissolvent, and believed therefore that one should go on to extract or crush the stone immediately. Leaving a fistula also had the advantage of affording a way for further exploration should it prove necessary subsequently.

Dr. R. T. Morris thought the ideal method of dealing with gall-stones was to cut down, expose and sew the gall-bladder to the abdominal wound, wait for adhesions to form, then open the bladder, remove what stones it might contain, and inject some fluid directly upon the stones in the duct which would cause them to dissolve. Thus the dangers of bile coming in contact with the peritoneum, of crushing the stone, and of further cutting or manipulation would be avoided. He was then experimenting with solvents of gall-stones with a view to finding one which would not injure the mucous membrane.

The discussion was continued after the reading of a paper by Dr. A. Vander Veer, of Albany, on "Report of Cases of Cholecystotomy with Special Reference to the Treatment of Calculus Lodged in the Common Duct," which will appear in a future number of the Record.

Dr. Louis Pilcher felt that the conditions which would make it prudent to perform the ideal cholecystotomy would rarely arise. He believed that in the great majority of instances it would be best to leave the opening in the gall-bladder patent for a time after stitching it to the parietal wound. He had done this in two instances in which he had removed a large number of stones, the result in both being successful.

Dr. Kellog had operated in two instances for supposed gall-stones, the symptoms including local pain, tumor, and jaundice. Yet no stones were present. In one the hepatic symptoms had been produced by pressure and occlusion of the gall bladder by surrounding adhesions, and the tumor belt was one of cancer of the head of the pancreas. In the other he found at the operation rupture of the gall-bladder which had been distended and presented a tumor. Several quarts of bile were found free in the abdominal cavity. There was also cancer of the pancreas in this case. The patient died.

Dr. Marcy recited two or three cases in which he had removed gall stones by operation, already published. In one case one of the stones impacted in the duct weighed as much as two ounces, being the largest on record as far as he knew.

Asepsis in Intraperitoneal Surgery.—Dr. William H. Wathen, of Louisville, in this paper gave specific directions for cleansing and preparing the operating-room, towels, instruments, person of the patient, surgeon and assistants, etc. The directions given looked toward cleanliness, and avoidance of infection.

Femoral and Ventral Hernia in the Female.—Dr. H. O. Marcy read a paper on this subject. He thought the advantages which McBurney had expected to gain by his method in inguinal hernia could be realized more fully in cases of femoral hernia. The anatomy of the parts seemed to demonstrate this. The author took a more hopeful view of the cure of both femoral and ventral cases than surgeons generally. The suffering experienced by those with ventral hernia justified an attempt at radical cure. The danger he thought should be no greater, where there were no adhesions, than in exploratory laparotomy conducted with modern aseptic care. Having operated in over one hundred cases he had never seen in ventral hernia any ill result come from resection of even a considerable portion of omentum, and in them the curative effect of firm closure of the opening had been shown, together with the advantages of tendinous sutures. He thought it was time to dispense with the drainage-tube.

Dr. Carstens had operated on one case of ventral hernia by encircling the hernial opening with a kind of corkscrew needle carrying a silk suture. The sac was dissected out in the usual way, and cut off short, then the wound was sewed up with catgut. The result had been good.

Drs. Asdale and Hall were afraid to dispense with the drainage tube, always employing it when in doubt.

Dr. W. W. Potter related a case of strangulated ventral hernia seen by him fourteen years ago. Bile was literally pouring out of the patient's mouth. The apparent reason of this was seen at the operation, when a portion of the liver was found in the hernial sac. When the sac was cut the liver retracted into the abdominal cavity with force. The patient recovered, the vomiting of bile ceased.

Drs. Carstens, Morris, and others thought there would be fewer cases of ventral hernia if laparotomists would take the precaution to sew peritoneum to peritoneum, muscle to muscle, etc.; but Drs. Ross and Rosenbaum thought it had not been demonstrated that in the resulting scar each of these tissues stood distinct in union, or that hernia was less likely.

Some Moot Points in Ectopic Gestation.—Dr. X. O. Werder, of Pittsburg, read a paper in which he gave the histories of a few cases operated upon by him, demonstrating that not all cases of ectopic gestation with rupture of the sac into the free peritoneal cavity terminated fatally, and also that in ectopic gestation with rupture an operation was not always called for, as the patient would be likely to recover without it. He would wait until further symptoms arose. Where ectopic pregnancy was recognized before rupture he would advise an operation, for one could not say in advance what cases would be safely let alone.

Trendelenburg's Posture in Gynecology.—Dr. Florian Krug, of New York, read a paper citing the advantages, in operating on the abdomen, of placing the patient in a position with the pelvis elevated at an angle of about forty five degrees, called Trendelenburg's posture. All his friends who had practised the method had become at once warm advocates of it. With the patient in this posture the intestines and abdominal contents in general fell toward the diaphragm and allowed the uterus, tubes, pelvic tumors, etc., to come readily into view.

Demonstration of Trendelenburg's Chair.—Dr. Willy Meyer, of New York, demonstrated Trendelenburg's chair, and warmly advocated resort to the posture bearing Trendelenburg's name in operations on the pelvic organs.

Ectopic Pregnancy—When Shall we Operate?—Dr. Rufus B. Hall, of Cincinnati, reported in this paper three cases because of their bearing on some interesting points. The first two were cases of suppurative cysts and adherent ovaries, in which the women of wealthy families had suffered long because their physicians had not the courage to advise an early operation, or feared to complete an operation, because of the extent of adhesions present. Nothing but an operation would give relief in such cases, and the earlier it was resorted to the more likely would the patient recover.

The third case was one of suppurative cyst in the pelvis,

which an operator had not removed because of the extent of the intestinal adhesions. After the patient was ready to enter the grave he obtained consent to operate, and with great difficulty overcame the intestinal adhesions so far as would enable him to excise the cyst-sac. The patient, however, died soon of intestinal obstruction. This case also illustrated the danger of delay, and of the necessity for going on and removing any tumor, unless malignant, after having entered the peritoneum, no matter what might be the adhesions or other difficulties met with.

Dr. Ross had met with two cases of pelvic abscess which he had drained through a laparotomy wound, and had been unable to get the tract of the drainage-tube to heal subsequently. In one he operated again, but was unable to overcome the firm intestinal adhesions. The patient died subsequently from chronic suppuration. It would seem, therefore, not always possible to go on and complete the operation.

Observations on the Surgical Management of Pelvic Abscess.—Dr. Charles A. L. Reed, of Cincinnati, gave a verbal abstract of a paper on this subject. The idea was prevalent, he said, that accumulations within the pelvis were restricted almost exclusively to the Fallopian tubes. This was one of the reactions from the old time pathology, which taught that everything was cellulitis. While he believed most cases of pus-collection in the pelvis occurred in the tubes, yet he was convinced the pus sometimes formed primarily in the cellular tissue. Such cases were the result of the accidents of labor. His paper contained histories of two cases in which the abscess had no connection with the tubes or ovaries, was extra peritoneal, and which was treated by an inguinal incision, and opening and draining extra-peritoneally, as one would incise in laparo-electrotomy, the finger within directing the knife. The appendages were healthy.

Drs. Rosenbaum, Carstens, and Mundé cited some personal experience with primary pelvic cellulitis.

Dr. Mundé said he could not agree with those who thought pelvic abscess could not occur except in the tube primarily, or that it did not sometimes occur primarily in the cellular tissue of the pelvis. Where plastic lymph formed a tumor which was immovable, it was probably extra-peritoneal; where movable, with mobility of the uterus up and down, it was probably intra-peritoneal. He was satisfied he had seen cases of collection of pus or of blood extra-peritoneal, and he thought to attack the accumulation extra peritoneally, or in the manner recommended by the author, was to be commended. How to prevent or cure sinuses, resulting perhaps from treatment of such cases of pelvic abscess, was something which he would gladly be taught.

Dr. McMurtry had never seen a case of true pelvic abscess; the pathological changes were such as to make it very difficult to demonstrate such a condition satisfactorily, even should it occur.

Dr. Joseph Price had not seen a case of pelvic abscess which was not primarily and secondarily tubal and ovarian. The ovarian affection was, in the vast majority of cases, secondary to the tubal disease. And as to pelvic hæmatocele, in operating in more than fifty cases of ectopic pregnancy, he had not yet found a case of so-called pelvic hæmatocele. In cases of so-called pelvic abscess and hæmatocele, a description had not been given of the exact condition of the tubes and ovaries, but it was suggestive that usually it was stated everything was matted together. Leaving the tubes supposed to be healthy might perhaps account for the cases of remaining sinus which Dr. Mundé had found a trouble.

Dr. Joseph Hoffman, of Philadelphia, took similar ground, and said that treatment by puncture through the vagina was, in almost every case, a losing game.

Dr. Egbert H. Grandin, of New York, had seen at least eight cases, probably twelve, of pelvic abscess, the origin of which, whether in the tubes or elsewhere, he did not claim to know, but he did know that they were cured by treatment per vaginam, without removal of the uterine appendages. In these cases the treatment from this direction was not a "losing game," since none of his patients died, but on the contrary all recovered symptomatically. The abscess was punctured, then the opening dilated by tearing, pus evacuated, partitions broken up by the fingers, hot water injected, and lately he injected peroxide of hydrogen, which destroyed the pyogenic membrane. Then drain. These patients, it might be remarked, had not been subjected to the risks of shock attending a laparotomy.

Dr. Reed said the terms pus-tubes and pelvic abscess should not be used interchangeably, as they denoted different conditions. He had seen only three cases of pelvic abscess, but felt sure of the nature of these.

A Plea for Early Hysterectomy and Puerperal Hysterectomy.—Dr. Joseph Price, of Philadelphia, read the paper, which claimed to be no more than a reasonable demand for early resort to exact surgery in the class of cases referred to in the title of the paper, which left to themselves went on from bad to worse. Cases were related in which tumors of different forms complicating pregnancy had demanded hysterectomy. If one would succeed, he said, he should treat every case as if it was the worst possible one, with much care and judgment, with no flurry for stage effects.

Dr. George Jackson Fisher had removed an ovarian tumor weighing more than the patient, over thirty years ago, and on that occasion he practised what he ever strongly advocated, strict cleanliness. Operate early, observe cleanliness, practise simple methods to attain success. He stated further that in reflecting on the life of our American physicians, the great mistake which they made was in giving themselves no diversion. Many lives had thus been cut short in the midst of their usefulness.

Further remarks were made by Drs. Cushing and Hoffmann, partly derogatory to electricity in the treatment of pelvic tumors.

Dr. Price repeated that while cleanliness was all important, it was difficult to attain. He loved a dude—but for his cleanliness only. McDowell was a dude in this respect. It was expecting too much of medical students to go forth and be cleanly in their practice after spending three years in the midst of dirt at medical colleges. He could pick out the physicians in his city who had no cases of puerperal fever from their personal appearance. Then, too much importance could not be placed upon simplicity, few instruments, etc.

Dr. Albert Vander Veer, of Albany, was elected president for the ensuing year.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 27, 1891.

O. D. Douglas, M.D., President, in the Chair.

Amendments to the By-Laws.—The Comitia Minora recommended in its report several changes in the by-laws, to be acted upon at the next meeting. It was recommended that there be a second Vice-President as well as first. The Comitia did not approve of the proposed by-law recommended by Dr. A. S. Hunter, namely, "it shall be the duty of the Committee on Hygiene to keep itself advised at all times concerning the condition of the public health, and on the outbreak of grave, infectious, or epidemic diseases to communicate to the public through the secular press such information and counsel as in its judgment the occasion may seem to demand."

Nominations were made as follows: For *President*, Drs. O. B. Douglas, L. Bolton Bangs, and George H. Fox; *Vice-President*, Drs. Seneca D. Powell, G. H. Fox, and C. L. Dana; *Secretary*, Dr. Charles H. Avery; *Assistant Secretary*, Dr. W. E. Bullard; *Treasurer*, Drs. John S. Warren, and Henry E. Crampton; *Censors* (five to be elected), Drs. Landon Carter Gray, W. M. McLaury,

Samuel Lloyd, W. H. Bates, A. F. Currier, C. C. Rice, S. O. Vanderpoel, G. E. Abbott, A. S. Hunter, H. E. Crampton, Richard Van Santvoord, W. C. Phillips, and Egbert H. Grandin.

The Surgical Treatment of Trachoma, with Report of Cases Treated by Grattage.—Dr. John E. Weeks read the paper. Trachoma, commonly called granular lids, was a most annoying disease to the patient, and one very difficult to treat without surgical measures. While non-operative treatment, by the use of astringents, etc., might materially shorten the duration of the disease in selected cases, yet the inflammatory condition which it excited was often very annoying to the patient and was not without danger. Sloughing of the cornea sometimes occurred.

With operative treatment, as recently developed, the prospects were more encouraging. Some of the methods would enable us to stop the progress of the disease, and even cure it without danger to vision, and without deformity of the lids.

For the sake of convenience he divided trachoma into three stages: 1, The period of formation of granules and follicles, absence of cicatricial contraction; 2, the stage when the granules had coalesced, vascular pannus with superficial keratitis had developed, evidence of cicatricial tissue in the conjunctiva, the tarsus somewhat swollen and thickened, etc.; 3, the trachoma tissue giving place to cicatricial tissue, sometimes entropion or complete stenosis, sometimes total blindness. His paper had to do with the first and second stages almost exclusively.

The surgical methods were considered in the following order: 1, Partial removal by excision; 2, partial removal by expression; 3, destruction of the trachoma tissue by scarification and electrolysis; 4, squeezing and brushing; 5, destruction of the granules by the galvano-cautery; 6, scarification and introduction of a strong germicide. Excellent results had been claimed for the first method, excision of the granules by the scissors, etc., but objections to it were that it removed only a portion of the diseased tissue; a portion of the conjunctiva was removed, which the patient, suffering long from the disease, could ill afford to lose, and it sometimes produced permanent ptosis. The hemorrhage was considerable. At present the advocates of the method are not numerous.

As to the second method—partial removal by expression—it had become quite generally employed, and was specially useful in the first stage. In practising expression the lids were everted and the granules pressed out by means of a forceps, of which those of Dr. Knapp, Dr. Noyes, and Dr. Gruening were most in use. Some applied sulphate of copper or astringents afterward. The conjunctiva remained red for some time, but this gradually subsided, and recovery took place with little trachomatous tissue remaining. A little shrinking took place. In select cases the method was very efficacious. Indeed, if it were applicable to all cases of trachoma it would leave nothing to be desired. But it was useless in older cases, where granules had coalesced and formed hard masses.

The third method, that by electrolysis, was used much by Johnson, of London, but it had the fault of not destroying all the trachomatous tissue, and of necessitating an expensive apparatus which might readily get out of order.

The method which the author wished to speak of in particular was partial removal by scarifying, and then rubbing in with a brush a strong germicide. This method has been used considerably in Paris. Its introduction was only recent. General anæsthesia was required; cocaine had sometimes been employed, but it failed to control pain. It might be necessary to do canthoplasty or canthotomy. By use of forceps and knife the conjunctival surface was scarified, the scarifications running parallel to the lids, close together, united by a few transverse incisions, the depth of the incision depending on the depth of the trachomatous tissue. The surface was then scrubbed thoroughly with a tooth-brush, carrying 1 to 500 bichloride solution. The two lids were then freed from clot, a bandage and antiseptic dressing applied. The bandage was removed at the end of twenty-four hours, and the surface rubbed with absorbent cotton dipped in 1 to 5,000 solution of bichloride. The same process was repeated a few times subsequently.

The author said that until within a few months his surgical experience had been confined to expression, but recently he had operated by grattage in over twenty cases, with much satisfaction. It was better suited to cases in the second stage than was expression. Each case required after-treatment according to its own merits. Where the scarifying process had left any cicatricial tissue, it was less, he thought, than would have resulted from the natural course of the disease, or as modified by ordinary treatment. The patients suffered no photophobia afterward, the bichloride caused no pain, the conjunctival surface was smooth and normal in appearance, and a fibrinous membrane formed which disappeared spontaneously. One of the striking results was the immediate cessation of discharge of any kind from the conjunctiva, converting the case from one of contagion into one of cleanliness. In a considerable number of the cases the conjunctiva did not become smooth until some time had elapsed.

Dr. Herman Knapp said the methods spoken of in the paper were old, but had not been thoroughly applied until recently. Grattage and scarification were ancient, but the rubbing in of a germicide was new. He had not himself performed grattage, and must confess that, according to the descriptions of it, the operation was to him repulsive. When thoroughly performed, he had read, the conjunctiva looked like velvet, with shreds hanging or projecting in every direction. It seemed to him there was more laceration of tissue than was necessary. The method which Dr. Knapp employed was expression, which he had resorted to in fifty-nine cases, in only one of which he had heard of a relapse taking place, one mentioned in the paper. If an antiseptic were used afterward, of course it might have a good influence, but he thought the mechanical action of expression by the roller forceps, and the tendency of nature to rid itself of the exudations, were the basis of the cure. Where the infiltrated tissue was too thick to permit of expression scarification might be necessary.

Dr. Emil Gruening had known of treatment by expression when a student, and had practised it considerably for five years, but until a later date he had found recurrence take place in a number of cases. The cure had remained permanent since he had adopted the custom of applying sulphate of copper after expressing the granules with his forceps, the sulphate of copper owing some of its efficiency doubtless to its germicidal influence. But in the second stage of trachoma, where cicatrices had formed, he thought expression was insufficient, and he meant to try grattage.

Dr. David Webster had of recent years used expression a good deal at the Manhattan Eye and Ear Hospital, more especially in cases of trachoma described by Dr. Knapp as having a frog spawn elevation without much secretion. His results had been very good. The operation must be performed thoroughly in order to secure success. He made it an object to squeeze out the contents of every granulation. Regarding the value of sulphate of copper applied afterward, he had requested his assistant to apply it to one eye in a given case, leaving the other untreated by this agent. The latter healed much more rapidly and with less reaction, and the final result was as good. He meant to try grattage.

Dr. Mittendorf said that the removal of masses of conjunctival tissue, canthoplasty, and canthotomy were sometimes attended by a certain degree of deformity, which in the case of girls might leave a disfigurement to be regretted for life. The operation of scarifying the conjunctival tissue was comparatively new, and we could

not yet say that there might not be resulting deformity. He had not, to his knowledge, left an entropion after his mode of treatment. Where the granulations were to be removed, it should be done by the method which involved the least injury to the tissues.

Dr. Martin spoke favorably of grattage, which he had witnessed in Paris; said no cicatrices were left at all, or they were thin, pliable ones, not as severe as those remaining after the long use of bluestone.

Dr. Harvey had assisted Dr. Weeks, and had himself performed grattage in sixteen cases, in only one there being a failure, due to the excessive depth of the scarifications and their wrong direction.

Dr. Weeks closed the discussion.

The Application of Antiseptics in Ophthalmic and Aural Surgery.—Dr. M. L. Foster opened his paper on this subject by quoting the definition of antiseptic and aseptic given by recent dictionaries, with the object of showing that those who now spoke sneeringly of antiseptics, while professing to believe in aseptics, failed to comprehend the meaning of the two terms, and in using inefficent germicides, or germicides in insufficient quantity, demonstrated want of confidence in their own theory and inability to establish asepsis in their surgical work. Antisepsis did not necessarily mean the use of corrosive sublimate or other powerful germicides. Experience had proven that the principle of antiseptics was correct. A strong germicide was not safe in the healthy eye, and while in ophthalmological surgery the addition of a weak germicidal solution might not be necessary, the secretions of the eye themselves keeping it in an aseptic condition as a rule, yet the addition of such a solution would contribute further to the safety of the eye, and should not be needlessly omitted. In the ear there was greater need for antiseptics, for here most operations were performed on tissues already septic, and incapable of being rendered proof against infection preparatory to the operation. The object was to remove dead tissue, establish free drainage, retard suppuration, afford protection, and carry out in a general way the treatment applicable to bone disease elsewhere.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 8, 1891.

H. M. Biggs, M.D., President, in the Chair.

Dr. Eugene Hodenpyl presented microscopical specimens taken from a tumor which had been removed from the upper lip of a man, fifty years of age. Five years ago, a pimple had appeared at the site of the present tumor, and soon after its removal, two years later, the present growth appeared. It was about four centimetres in its lateral diameter, and three centimetres antero-posteriorly; it was lobular, and quite hard. The microscopical appearances were quite remarkable, as different portions of the tumor presented respectively, myxomatous, cartilaginous, glandular, and sarcomatous tissue. Such a tumor in this region he considered to be exceedingly rare. It had apparently originated in the sweat-ducts. The connective tissue was principally derived from the fibrous capsule. The existence of typical cartilage was very interesting, and not very common, although he had recently had a specimen from the pia mater of the spinal cord, in which such masses were found.

Dr. T. M. Prudden said, that hand in hand with the proliferation of the glandular elements, it was not unusual to have simple hyperplasia of fibrous tissue, and from this there might be a development of cartilaginous tissue, a metaplasia. The specimen presented showed just such a tissue as one might expect to develop in this way.

As to the question whether it is to be classed as a sarcoma, he could only say that such tumors are on the border line, and myxomatous tissue is so closely allied to certain varieties of sarcomatous tissue that when hyperplasia is added to this the difficulty of differentiating it from sarcoma is rendered still greater.

A Case of Infantile Spastic Hemiplegia.—Dr. E. Fisher presented the brain from such a case. The patient, who was a woman, thirty-two years of age at the time of her death, gave a history of having been paralyzed since she was about two years of age. On examination, the usual condition of the cerebral hemiplegia of childhood was found, the paralysis in this case being on the right side of the body, more or less marked in the face, and accompanied in the extremities by a spastic condition of the muscles, and by exaggerated reflexes. There were some athetoid movements, which, however, were not especially noticeable except upon the patient's attempting to do something with the hands. She also exhibited, as many of these patients do, marked mental weakness.

The specimen showed the left hemisphere to be very much atrophied, especially all that portion posterior to the fissure of Rolando, the left ventricle was dilated, and portions of the cortex had almost entirely disappeared. There was also marked atrophy of the opposite lobe of the cerebellum. The degeneration following upon this atrophy could be traced with the naked eye through the crus and pons into the cord, where there was marked degeneration of the opposite half of the cord, the motor tract.

The causes usually given for this infantile spastic hemiplegia of cerebral origin are meningeal hemorrhage and encephalitis. The former commonly occurs as a result of cerebral pressure during a tedious labor or, less frequently, from instrumental delivery, while the latter necessarily occurs after birth, and most commonly during the second year, either idiopathically or as a sequela of one of the exanthemata. It was almost impossible at so remote a period after the occurrence of the lesion, to say what was the origin of the condition presented in his case, but he was of the opinion that there had either been a meningeal hemorrhage, or an occlusion of the middle and posterior cerebral arteries.

In answer to a question from Dr. Armstrong, as to whether the configuration of the skull indicated the configuration of the brain, Dr. Fisher replied, that this was one of twenty cases in which cranial measurements had been taken, and in this case it had been found that on the side corresponding to the cerebral lesion the skull was decidedly smaller; it was not microcephalic, but only asymmetrical.

Dr. S. T. Armstrong thought that if a meningeal hemorrhage had occurred, some trace of it, such as a deposit or a discoloration of the meninges would have been left; and again, if the condition were due primarily to occlusion of the blood-vessels, he thought, even the existence of an extensive collateral circulation ought not to have entirely obliterated the original trunks.

The asymmetry of the skull suggested the possibility of early ossification as a cause of the atrophied condition of the hemisphere, and also suggested the possibilty that an early operation might have resulted in a better development of the brain.

The President said that, as a rule, he thought a surface hemorrhage would leave some pigmentation of the meninges, but that after so long a period it was likely that even if important vessels had been occluded, the small vessels would have become so enlarged and the original ones so atrophied that it would be impossible to determine the original cause of the trouble.

Dr. Fisher said that he did not think in this case, the asymmetry of the skull was the cause of the atrophy, but rather was consequent upon the cerebral lesion.

The President presented the brain from an Irish woman, twenty-six years of age, who had been admitted to the hospital on February 14, 1891. Her family history was good, she had been in good health previously, and denied having had syphilis. Just previous to her admission, being a prostitute, she had had sexual intercourse, and a few

moments after this she was seized with intense pain in the head, the left arm and leg became weak, and she fell. At the same time her sight was affected, and sensation was lost on the left side, but she did not become unconscious. On admission, it was found that the left side of the face and the left arm and leg were paretic, that the head constantly rotated to the right, that sensation was abolished on the left side, and there was left hemiopia. For the first two weeks following her admission, she was given large doses of iodide of potassium, and there was apparently some improvement in motion and sensation and in her general condition, but she was noisy, and at times delirious. After this, she grew steadily worse; the pulse was rapid, the temperature rather high, and she became stupid, so that it was necessary to resort to rectal alimentation, and to drawing the urine. Shortly before death, her temperature reached 106.8° F., and her respirations were 97.

At the autopsy, the thoracic and abdominal organs showed nothing of importance. On the posterior branch of the right middle cerebral artery was a tumor about the size of a pea, completely surrounding this vessel. The temporo-sphenoidal lobe was very much softened internally, and when a small opening was made, there was a discharge of blood-stained sero-purulent matter, and an examination of this fluid, showed that it contained a great many white corpuscles, disintegrated brain matter, and blood-pigment, both granular and crystalline. On section, the brain showed a cavity extending from the apex of the tempero-sphenoidal lobe nearly to the occipital lobe, and the area of softening extending into the occipital lobe and forward to the frontal lobe. There had evidently been an old hemorrhage, for after section, and while the specimen was still fresh, pigmentation could be clearly seen around the margins of this cavity. There had also been a recent hemorrhage into the cavity. Although the growth had not yet been examined microscopically, Dr. Biggs thought the history left but little doubt that it was a gumma.

Of course, the growth must have existed for some time, and the sudden onset of the symptoms in this case was best explained on the supposition that there was a sudden shutting off of the blood-supply, consequent upon the excitement attendant upon the sexual intercourse. He was of the opinion that thrombosis did occur in this way, for he knew of two instances in which thrombosis of the sinuses followed directly upon very unusual excitement, and where there was apparently no other cause. In one of these cases, the thrombosis occurred in the straight sinus. This was only the second time in which he had seen thrombosis of this sinus In this case, it was clear from the history that the thrombosis was directly due to very severe mental disturbance.

Stated Meeting, April 22, 1891.

H. M. Biggs, M.D., President in the Chair.

The Anatomical Changes of Cured Phthisis.—Dr. H. P. Loomis presented the lungs from four cases to illustrate these changes. The frequent presence of these lesions in post mortem examinations gave ground for the belief that many more persons recover from tuberculosis than would appear from clinical observations. Out of 524 autopsies at Bellevue Hospital on persons dying of non-tubercular diseases, 43, or eight per cent. presented in the lungs the changes which he considered characteristic of healed tuberculosis. Dr. Austin Flint had stated that out of 640 cases of phthisis 43, or 6.5 per cent., recovered, and Dr. Williams, of London, reported that out of 1,000 cases 4.6 per cent. were cured. The question of the existence of tubercle bacilli in these apparently healed areas could only be satisfactorily demonstrated by inoculation experiments, and in the few experiments of this kind which he had made these bacilli were not found.

The first specimen showed at the apex of the right lung a dense, circumscribed, circular nodule, three-quarters of an inch in diameter, surrounded by laminated fibrous deposits, and presenting the appearance of a solid cicatrix formed of cartilage. The nodule was situated in the substance of the upper lobe, but connected with the puckered and depressed pleura by easily recognized bands of new connective tissue. The lungs were normal.

In the second specimen, contracted and disintegrated areas were scattered throughout the upper lobe, in which no remnant of pulmonary tissue could be found. The remaining portions of the lungs were normal. Broad white septa of dense fibrous tissue traversed this upper lobe in every direction, the bronchi were dilated, and their walls enormously thickened, and a small contracted cavity with walls one-eighth of an inch thick was found near the apex.

The third specimen showed a healed cavity two inches in diameter in the upper lobe. It was closed in on all sides, and lined by a dense fibro-cartilaginous false membrane, which, in places, was one quarter of an inch in thickness. No bronchus could be found opening into the cavity. The walls were trabeculated, and vegetations projected from them, while in the most dependent portions of the cavity, some grumous, cheesy material had collected. The surrounding pulmonary tissue was indurated and infiltrated with black pigment, but the other portions of both lungs were normal.

In the fourth specimen the upper lobe, which was normal in other respects, presented a cavity one and a-half inch in diameter, having perfectly smooth walls. There was but little connective tissue surrounding this, and a microscopical examination revealed the interesting fact that the cavity was lined with ciliated epithelium, and that it was therefore a dilated bronchus, and not the result of tubercular destruction of tissue. Dr. Loomis said that this was only the second specimen of the kind which he had seen.

The President said there was no question about these specimens being tubercular, and he believed with Dr. Loomis that they were of very frequent occurrence, but he would place the percentage considerably higher; for in at least twenty per cent. of the cases dying from non-tubercular disease in the charity hospitals of this city he found these old cheesy, calcareous nodules in the upper lobes of the lungs.

Dr. T. M. Prudden also thought these lesions were very frequently met with. Their exact significance could be best determined by a comparison of such post-mortem statistics with accurate clinical records. He did not think it was hardly desirable to speak of all such lesions as those of "cured phthisis," for cases in which living tubercle bacilli were found would be more accurately described by calling them cases of tuberculosis in abeyance.

First Aid to the Injured.—We have in this city and elsewhere in the country a system of instruction, described as "First Aid to the Injured." This instruction consists of a series of five lectures, followed by an examination conducted upon the basis of a text-book, with which the pupils are provided at the commencement of the course. Attendance upon these lectures is as a rule free, and they are delivered before various clubs — working-girls' clubs, young men's associations, policemen's classes, and classes otherwise made up. The association which supplies the lectures is supported by contributions, applied to the office expenses and various incidentals, the physician's work in giving the instruction being gratuitous. We have had a number of gratifying reports from the pupils who have taken these courses. Instead of a panic in the presence of injuries or convulsions, even young girls promptly apply the simple remedies, or do what they have been directed to do for the comfort of the patient. The intelligence and practical assistance rendered by policemen upon occasions of street injury has been publicly commented upon.—*The Nightingale.*

Correspondence.

CATS AND THE PROPHYLAXIS OF RINGWORM AND FAVUS.

To the Editor of the Medical Record.

Sir: Though it is a fact universally acknowledged that ringworm and favus are communicated to man by some domestic animals, especially cats, prophylactic measures in this direction are somewhat neglected in our hospitals and public institutions. Since my attention has been attracted to this interesting subject (see my paper, "The Prophylaxis of Ringworm," *New York Medical Journal*, July 13, 1889), I have had occasion to repeatedly trace individual cases, as well as small epidemics, of ringworm and favus to their original source—a cat. Two cases of favus, contracted from a cat, have lately come under my observation, and prompt me to sound a warning and urge a stricter prophylaxis.

The cat which had given the disease to two American boys, brothers, two and one year old respectively, suffered from favus of the ear. The disease had destroyed the pointed end of the right ear, and the resulting sore was surrounded by a crown-shaped mass of yellow scutula half an inch thick. Both boys had typical spots of favus on the right thigh and in the middle of the abdomen, respectively.

Favus is by no means solely an imported disease, as is often stated erroneously. It is a disease peculiar to mice, which in turn communicate it to cats.

Some of our hospitals abound with cats, which, as the children's pets, enjoy considerable freedom, and not infrequently, I think, start an epidemic in wards far removed from any other source of contagion.

Let, therefore, the number of cats be limited in public institutions and hospitals; put parents and nurses on their guard as to the possibility of danger arising through the presence of cats, and urge them to be quick in removing all animals with suspicious symptoms. These prophylactic measures, if properly enforced, will protect our children against ringworm and favus, both such obstinate and disgusting diseases.

Fred. J. Leviseur, M.D.

687 Lexington Avenue.

PERFUMERY IN "HAY FEVER."

To the Editor of the Medical Record.

Sir: At this season of the year there are many persons who are sorely afflicted with hay fever. Such persons naturally wish to avoid anything and everything which may have a prejudicial effect upon them, for, at its best, life is at a discount during "sneezing time." Being a sufferer myself, I know whereof I speak. Now for the point I wish to make: Perfumery used on the handkerchief is about as good a sneeze-producer as can be found. It surpasses ragweed, golden-rod, and everything else I know of. The only advantage it has is its pleasant odor, but that don't compensate for the twenty or thirty sneezes it induces. Beware of perfumery, if you have hay fever, till your nose shall have ceased to respond so energetically to excitants of various sorts.

Joseph William Stickler, M.D.

Orange, N. J.

COLIC NOT NECESSARILY A SYMPTOM IN GALL STONES.

To the Editor of the Medical Record.

Sir: The case of "Colic not a Necessary Symptom in Gall-stones," reported in the Record of September 12, 1891, page 302, from the clinic of Mr. Lawson Tait, calls to my mind a very unique case that came to my notice some time since, and was similar in that there were a great many gall-stones, without colic.

This man, Dr. C. B——, was admitted to the hospital of the Michigan State Prison, January 30, 1890, supposed to have pulmonary phthisis. He was put upon quinine, iron, cod-liver oil, and whiskey. He did not improve, and, February 26, 1890, while lying on the bed talking to an attendant, turned over and died without a struggle. Twelve hours after death I saw him for the first time, and made an autopsy. The body was much emaciated. Marks on the lower part of abdomen and penis, supposed to be scars of old venereal sores. Left foot and leg badly swollen. Both lungs were completely filled with tuberculous deposits and large abscesses filled with thick, milky pus, and were firmly adherent to the thorax on both sides. The heart was slightly enlarged, and in the apex was an abscess one inch in length, containing two drachms of milky pus. The liver was much enlarged, and the capsule was easily stripped off. The gall-bladder was thickened, and contained three hundred and fifty-three gall-stones, from the size of a hemp-seed to that of a large acorn, and weighing in all seven hundred grains. One stone, weighing ten grains, was packed so firmly into the cystic duct that the duct was torn to get it out. The other organs were normal. He had had no pain in abdomen, and no symptom that led the attending physician to suspect any trouble with the liver, gall-bladder, or ducts.

Respectfully,

W. W. Lathrop, M.D.,
Physician of Michigan State Prison.

THE HAGEDORN NEEDLE.

To the Editor of the Medical Record.

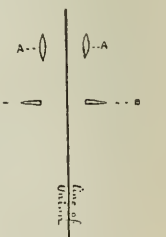
Sir: In a letter on "How to Keep Needles from Rusting" (by immersion in alcohol), published several weeks ago in the *New York Medical Journal*, I mentioned the "self-threading" Hagedorn needles as being, in my judgment, best for general use, and a decided comfort, as they can easily be threaded even with fingers sticky from blood, and in a very bad light.

I infer from several inquiries that this style of needle is not generally known in New York. In fact, a large surgical-supply house in this city said that my order of some six months ago was the first they had ever received. Nevertheless, this kind has been used in Germany several years. There they are called "Nähnadeln mit federndem Ohr."

The accompanying sketch (Fig. 1) will give the idea. The thread is snapped into the posterior of the two eyes, as the steel here is not continuous, although the two sides touch. When properly made the eye does not cut the thread. The anterior eye is only for use, threading it as an ordinary needle, in case the other eye accidentally breaks. It may be allowable in this connection to repeat the explanation as to why the Hagedorn is preferable to the surgical needle still in common use.

Fig. 1.

Fig. II.



A, in Fig. 2, is the needle-hole made by the latter kind; *B* is the Hagedorn needle-hole, the long axis of which is at right angles with the line of union—like the button-holes along the edge of a coat.

It is evident that when the suture is tightened *A* will be made to gape thereby, whereas *B* will be closed, hence tending to check bleeding from the stitch-holes, and making the subsequent scar a smaller one.

Very respectfully,

Robert H. M. Dawbarn, M.D.

345 West Fifty-Sixth Street.

PROFESSOR LEYDEN, OF BERLIN.

To the Editor of the Medical Record.

Sir: On my return from Berlin I notice in a letter from me, while abroad, mention is made of my friend Professor Leyden as being interested in the study of influenza, which is quite true; but unfortunately, by an almost inexplicable misprint, I am quoted as saying that he is a monomaniac on the subject. Of course anyone who knows his thorough methods would consider this to be impossible, even by a strain of pleasantry in the license of a friendly letter. Trusting that you will disavow any intention on my part of being discourteous to the distinguished counsellor,

I am, yours truly,

Louis Fischer, M.D.

40 Rivington Street.

HOW DOES ETHER KILL?

To the Editor of the Medical Record.

Sir: In the Record of September 19th you say that there was a death from ether in your city September 9th, although before administering the ether a careful examination had failed to reveal any disease of the heart. Quite likely. The very best heart in the world will cease to beat if the lungs fail to perform their functions, and therefore only poisonous blood is brought to the circulatory nerve-centres. And as is generally known (or as should be generally known), ether paralyzes first the respiratory nerve-centre, and when respiration ceases the heart continues to beat for as long a time as the blood is not too impure to produce the proper stimulus in the circulatory centre; but when the blood, from lack of aeration, becomes too impure, the heart ceases to beat, whether sound or unsound, and life ceases also. If this fact were more constantly borne in mind by persons administering ether, fewer deaths would occur to report.

Respectfully,

S. L Kilmer, M.D.

South Bend, Ind.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 13, 1891, to October 3, 1891.

Vollume, Edward P., Colonel and Chief Medical Purveyor. Retired from active service. S. O. 211, A. G. O., Washington, D. C., September 11, 1891.

Crampton, Louis W., Assistant Surgeon. Relieved from duty at Fort Sheridan, Ill., and ordered for duty at Fort Townsend, Wash., relieving Assistant Surgeon James C. Worthington.

Worthington, James C., Assistant Surgeon. Being relieved, is ordered to Fort Thomas, Ky., for duty at that station, relieving Assistant Surgeon George M. Wells.

Wells, George M., Assistant Surgeon. On being relieved from temporary duty at Fort Thomas, Ky., is ordered to San Carlos, Ariz., for duty.

Kean, Jefferson R., Assistant Surgeon. Granted leave of absence for three months on surgeon's certificate of disability.

Wells, George M., Assistant Surgeon. Relieved from duty at Columbus Barracks, O., and ordered to Fort Thomas, Ky., for temporary duty, relieving Assistant Surgeon Henry I. Raymond.

Raymond, Henry I., Assistant Surgeon. On being relieved from duty, to report to the commanding officer, Fort Robinson, Neb., for duty at that station.

DeWitt, Theodore F., Assistant Surgeon. Granted leave of absence for six months on Surgeon's certificate of disability.

Ewing, Charles B., Assistant Surgeon. Will continue on duty as Attending Surgeon and Examiner of Recruits at St. Louis, Mo.

Crosby, William D., Assistant Surgeon. Relieved from duty at Fort Pembina, N. D., and ordered to Fort Missoula, Mont., for duty.

Reed, Walter, Captain and Assistant Surgeon. Relieved from duty as Attending Surgeon and Examiner of Recruits at Baltimore, Md., and ordered to Fort Snelling, Minn., upon completion of his duties as member of Army Medical Board.

Kimball, James P., Surgeon. Relieved from duty at Fort Supply, I. T., and ordered to Fort Clark, Tex.

Patzki, Julius, Surgeon. Relieved from duty at Fort Huachuca, A. T., on expiration of present sick leave. and ordered to Fort Supply, I. T.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 3, 1891.

Hoehling, A. A., Medical Inspector. Ordered as member of Medical Examining Board.

Harmon, G. E. H., Surgeon. Ordered to the Yorktown.

Boyd, John C., Surgeon. Detached from the Yorktown, and granted leave of absence.

DuBois, F. L., Medical Director. Detached from Navy Yard, Portsmouth, N. H., and to wait orders.

Avers, J. G., Surgeon. Detached from the Wabash, and ordered to Navy Yard, Portsmouth, N. H.

Cordeiro, F. J. B., Passed Assistant Surgeon. Ordered to the Wabash.

Norton, O. D., Passed Assistant Surgeon. Ordered to the Petrel.

Marsteller, E. H., Passed Assistant Surgeon. Detached from the Petrel, and granted leave of absence.

Hall, John H., Surgeon. Ordered to appear before the Retiring Board.

Turner, Thomas J., Medical Director. Placed on retired list, September 21, 1891.

Hall, J. H., Surgeon. Placed on retired list, September 25, 1891.

Boyd, J. C., Surgeon. Ordered to duty on Naval Medical Examining Board.

Marsteller, E. H., Passed Assistant Surgeon. Detached from the Petrel and granted one month's leave.

Norton, O. D., Passed Assistant Surgeon. Detached from special duty at the Naval Academy and ordered to the Petrel.

Hall, J H., Surgeon. Detached from Naval Hospital, Chelsea, Mass., and placed on waiting orders.

Bradley, G. P., Surgeon. Ordered to Naval Hospital, Chelsea, Mass.

Gravatt, C. U., Surgeon. Ordered to Naval Hospital, Brooklyn, N. Y.

Gardner, J. F., Passed Assistant Surgeon. Detached from Naval Hospital, Brooklyn, N. Y., and ordered to the Naval Station, New London, Conn.

North, J. H., Assistant Surgeon. Detached from Navy Yard, New York, and wait orders.

Lung, George A., Assistant Surgeon. Detached from Naval Station, New London, Conn., and ordered to the Navy Yard, New York.

Simons, M. H., Surgeon. Detached from the Enterprise and ordered to hold himself in readiness for sea service.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 3, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	65	11
Scarlet fever	48	6
Cerebro-spinal meningitis	3	2
Measles	38	5
Diphtheria	75	26
Small-pox	2	0
Varicella	2	0
Pertussis	2	8
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

A Morbid Viennese Custom.—It appears that a somewhat morbid custom exists among the Viennese of having the dead bodies of children and other persons dear to them photographed, and for this purpose the corpse used to be taken to the photographer's studio. The attention of the sanitary authorities having been drawn to the danger of the dissemination of infectious disease by this practice, a decree has been issued by the Austrian Minister of the Interior absolutely forbidding the photographing of corpses in studios open to the public, and the photographing of bodies of persons who have died of any infectious disease by professional photographers, even in private houses. Exception is made of cases in which such photographs may be required for police or medico-legal purposes. In the case of persons who have died of non-infectious disease, the corpses may be photographed at the private residence of the deceased, subject to the approval and on the responsibility of the medical official whose duty it is to verify deaths.

Birds as Surgeons.—Some interesting observations relating to the surgical treatment of wounds by birds were recently brought by M. Fatio before the Physical Society of Geneva. He quotes the case of the snipe, which he has often observed engaged in repairing damages. With its beak and feathers it makes a very creditable dressing, applying plasters to bleeding wounds, and even securing a broken limb by means of a stout ligature. On one occasion he killed a snipe which had on the chest a large dressing composed of down taken from other parts of the body and securely fixed to the wound by the coagulated blood. Twice he had brought home snipe with interwoven feathers strapped on to the site of fracture of one or other limb. The most interesting example was that of a snipe both of whose legs he had unfortunately broken by a misdirected shot. He recovered the animal only on the day following, and he then found that the poor bird had contrived to apply dressings and a sort of splint to both limbs. In carrying out this operation some feathers had become entangled around the beak, and not being able to use its claws to get rid of them, it was almost dead from hunger when discovered. In a case recorded by M. Magnin, a snipe which was observed to fly away with a broken leg, was subsequently found to have forced the fragments into a parallel position, the upper fragments reaching to the knee, and secured them there by means of a strong band of feathers and moss intermingled. The observers were particularly struck by the application of a ligature of a kind of flat-leafed grass wound round the limb, of a spiral form and fixed by means of a sort of glue.

A Strong but Innutritious Diet.—An autopsy made on the body of an Arab stowaway found on a ship in the Thames furnished no signs of disease in the brain or the chest, except a few old adhesions in the left pleural cavity. The gall-bladder was very distended and full. Three small ulcers existed on the anterior coat of the stomach. Several patches of inflammation were found in the small intestine. In the cæcum were found twenty trousers buttons, three cog-wheels (apparently out of a watch, two of them one inch in diameter—these were doubled), one 2-inch steel screw bent double and one 1-inch screw, six pieces of a lock (the biggest piece was 1½ inch long and ½ inch broad), a circular piece of brass (1¾ inch in diameter folded into four), several pieces of iron wire (four were 1½ inch in length), brass, and lead, and two key tallies on a ring, one inch in length. In the ascending colon, about five inches from the cæcum, were found a piece of steel wire one-eighth of an inch in diameter, and three inches and a half in length, bent double, and one small cog-wheel. The weight of these bodies together amounted almost exactly to half a pound. The body was much emaciated; no subcutaneous fat was present in chest or abdominal walls, or any fat round the kidneys. The deceased was quite unknown; no particulars could be discovered by the police employed to obtain evidence for the purposes of the inquest. There was no perforation of intestines, or any sign of disease in the colon.—*The Lancet.*

Morbid Winking by Miners.—Dr. Snell persists in his opinion that there is no reason for supposing that nystagmus or the nervous disease which manifests itself in a morbid winking of the eye, so common among miners, is attributable to working by the imperfect light of the safety-lamp. The fact that the complaint is found among the workers with naked lights is in itself sufficient to throw doubt upon the long-prevalent theory. The Government Inspector of Mines for the Midland District notes, on Dr. Stokes's authority, the case of a man who, after working with the Davy lamp for fourteen years without injury, proceeded to work at a pit where candles were used. He had been employed there for some three and one-half years, and during the last twelve months he experienced symptoms of nystagmus, and had ultimately to leave work and seek medical aid. Dr. Snell has collected a mass of facts and a record of a large number of instances of men suffering from the affection, which will, he believes, be very corroborative of the views he has before set forth, namely, that the prime cause of the affection is to be found in the position assumed by the miner at his work.

The Water in Florence all Condemned.—The commission charged by the municipality of Florence to examine the water-supply of the city, after a thorough and prolonged study, has just made a report in which all the existing sources of the supply are condemned. The Montereggi aqueduct, which comes from above Fiesole, is declared to be a permanent danger to the public health, and the water from that source ought to be definitely abandoned. With regard to the other supply, which is known as the Anconella, on the south side of the Arno, though better than the former, it is not possible to save it from all the causes of contamination which render it suspicious and may, eventually, make it dangerous and unfitted for domestic uses, and the commission advises the most speedy suppression of it for these uses. The wells have long been known as poisonous, and there is no other water-supply attainable without the construction of a new aqueduct, which will require time and money. This is a satisfactory commentary on the rancor shown by the Florentines to the exposure of the insanitary condition of their city by the *Times*. Only bottled waters should be drunk by visitors to the Tuscan capital if they would avoid the risk of typhoid fever.

I'm going into partnership
With a lovely young M.D.,
She brought me safely through the grip,
And now she'll marry me.
She'll keep her practice as before,
She's wise in everything;
And as for me—I'll tend the door
And do the marketing!

THE PHYSIOLOGICAL RELATION OF ALCOHOL TO FOOD, AND ITS PROPER USE IN MEDICINE.[1]

BY WILLIAM HENRY PORTER, M.D.,

PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

MR. PRESIDENT, LADIES AND GENTLEMEN: This question as to the physiological relation of alcohol to food is one of both scientific and vital importance to the human race. Before it can be discussed, however, with anything like an approach even to practical accuracy, a definite conception of the composition of the so-called food-stuffs is necessary.

The term food must not be used in a vague and meaningless manner, but in such a way that a concise composition will be indicated. When this has been accomplished, a sound and lasting chemico-physiological foundation can be established from the chemical substances which both the chemist and physiologist teach are essential for the perfect growth, development, and maintenance of animal life and its vital powers. The true position held by alcohol in its relation to food can be correctly stated, and its use and abuse, both in health and disease, accurately defined. By understanding fully the true utility of food, the physician can then say just when alcohol can be administered to advantage, and when and why its use should be avoided. His assertions are now based upon sound and fully explained chemico-physiological laws, and appeal not only with clearness but with absolute positiveness to every intelligent mind.

It is also pleasant to note, under these conditions, how rapidly the day recedes which calls for the necessity of trumping up some unknown, vague, and totally undemonstrable poison in connection with the use of alcohol, by which, in some mysterious and almost devilish manner, all its damaging effects upon the system were induced.

One of the questions, however, to be settled first is, what substances shall be considered as food-stuffs, and which are to be omitted from the list. The only satisfactory method by which this can be accomplished is to commence our study with the elementary proximate principles. Following this plan, we find that the fundamental food-stuffs are naturally divided into three well-defined and distinct classes.

The proximate principles form four separate and essential groups, and two accessory classes of compounds, in one of which the common waste products are found, in the other, the by-products, including the leucomaïnes and ptomaines. As the last are results rather than an essential part of normal physiological vitality, they can justly be omitted altogether at this time.

1st. The inorganic proximate principles such as water and the inorganic salts, viz., the chlorides, phosphates, carbonates, sulphates, etc. These elements all enter the body under their own form, are not oxidized or split up within the system to form other compounds. They act as it were mechanically, and after having served their purpose in the body, they pass out of the system with the excretions absolutely unchanged in their chemical composition.

2d. The CHO class of proximate principles, or those which have for their composition the elements, carbon, hydrogen, and oxygen only, such as fats, sugar, and starch. In the native fluid of the body, milk, there are, however, only two, fat and sugar—the latter in the form of lactose. By many writers upon food and digestion alcohol and the vegetable acids and salts are included in this group of food-stuffs, because in their chemical construction they are formed out of the same elements, carbon, hydrogen, and oxygen; and also for the reason that they undergo nearly the same changes within the system, the final product of elimination being practically identical with all the other CHO compounds. Notice, however, is here given that an exception will be taken to the admission to the list of food-stuffs of these substances, especially of alcohol, which will be more fully explained later.

3d. The CHNOS class of proximate principles, or those which have for their chemical composition carbon, hydrogen, nitrogen, oxygen, and sulphur. The common representatives of this group of food-stuffs are called proteids, and consist of the albuminous parts of milk, eggs, and meats of all kinds, the latter including, both chemically and histologically, fish, lobsters, crabs, turtles, oysters, clams, poultry, game, etc. We also include the nitrogenous or albuminous parts of plant life under the common name, vegetable proteid.

4th. The CHNO and CHNOFeS class of proximate principles, composed of carbon, hydrogen, nitrogen, and oxygen, and those which have an element of iron, or of iron and sulphur, or sulphur alone added to the CHNO compound. These substances, however, do not particularly concern us as food-stuffs, although they do enter into, and are essential for the formation of, the various pigments and coloring matters of the blood and tissues.

In regard to the exact mode of origin and absolute formation of these bodies, we have no definite knowledge from a chemical basis, and it is not necessary that we should enter minutely into the details of this question as regards alcohol and food. That they exist within the body and are of vital importance is unquestioned. But they do not of necessity enter into the composition of the food-stuffs.

To understand accurately the relation of alcohol to food, we must first appreciate the exact composition and uses to the system of the substances which are entitled to be named food-stuffs. Then we must fully understand what changes occur in these substances while they are passing through the body, and also what results are to be obtained while they are being carried through this transitional process. We must know whether they act simply mechanically, or are split up to yield only heat and energy, or are developed into the various body-tissues and gland-structures.

Before this information was at our command we were simply dealing with theoretical assumptions; but when able—as we now are—to assert positively what follows upon the introduction of a CHO compound, like fat, sugar, and starch, into the animal economy, we can speak with an absolute degree of certainty. The results are now as positively known when a similar CHO compound like alcohol is introduced into the system.

At this point table I. is introduced, that we may have clearly before us the true composition of the articles commonly rated as food-stuffs. Also tables II., III., IV., and V., which significantly demonstrate the chemical composition and the results of the oxidation of the

[1] Read before the National Temperance Medical Congress, Port Richmond, July 15, 1891.

CHO and the CHNOS compounds, together with what they furnish to the body by the cycle of changes through which they pass to form the final or excrementitious bodies to be eliminated from the system.

TABLE I.—*Comparative Table of Food stuffs.*

Kind of Food.	Water H_2O.	Proteids CHNOS.	Starch, Sugar, and Cellulose CHO.	Fats or CHO.	Mineral Salts.
Human milk	88.28	3.41	4.62	3.48	0.21
Cow's milk	86.23	3.73	4.93	4.50	0.60
Skimmed milk	88.00	4.00	5.04	1.80	0.80

TABLE III.—*Results of Oxidizing CHO Compounds.*

Fats, sugars, starches, and alcohol } yield to the body { Heat, energy, and rotundity, and act as lubricating agents, } and are excreted from the body as { carbon dioxide and water.

By this arrangement of our chemical and physiological knowledge we find that the CHO class of substances, introduced as food-stuffs or otherwise, are in the strict limitation of the term non-nutritious elements. They are all stimulating compounds yielding to the system, by their conversion into alcohol like by-products, and by their final oxidation into carbon dioxide and water, heat, energy, lubrication, and rotundity. This latter condition is brought about by the oil-globules being stored up mechanically within the interstices of the white fibrillated connective-tissue substance. They also act as mechanical lubricants, and when kept within physiological bounds aid in sustaining those vital forces by which the proteids, or true nutritive food-elements, are converted into the various structures constituting the animal organism.

When the CHO compounds are taken in excess of the absolute demands of nature, they all tend to stimulate—some more than others—weaken vital action, and present a perfect proteid metabolism, causing to be developed from this incomplete transformation of the CHNOS substances an almost unlimited number of poisonous compounds. Nutrition is now decidedly impaired, and a vast number of pathological problems developed, the discussion of which, although important and interesting, would carry us far beyond the limits of this paper.

A single glance, however, at our proteid tables number IV. and V. illustrates an entirely different result.

Out of these CHNOS compounds alone, as illustrated by table V., we find all tissue-formations and gland-structures are developed.

Or, speaking more correctly, we should combine with them in a mechanical manner some of the mineral substances of our first class, as is the case in the formation of bone-tissue, etc. But even here the two groups are kept separate and distinct so far as any chemical union is concerned.

TABLE V.—*Results of Oxidizing CHNOS Compounds.*

The proteids $C_{72}H_{112}N_{18}O_{22}S$ { are developed into all forms of bodily tissues, } yielding { heat, energy, muscular and glandular activity, } and are excreted from the body as { urea, uric acid, kreatinine, carbon dioxide, water, and sulphuric acid as sulphates.

The fats, sugars, and starches do not join either with free nitrogen or nitrogenous compounds to form proteid bodies. At one time this was supposed to be the case, because by artificially exercising a muscle under a closed bell jar carbon dioxide was obtained. But as carbon dioxide is one of the natural products resulting from ordinary proteid oxidation—as shown in Table IV.—it is far more reasonable to argue that the CO_2 so acquired comes direct from the proteid body, than to attempt in some unexplainable manner and by a method totally in opposition to well-known chemical laws, to bring it from some other source. In fact, chemistry further teaches that these CHO substances are rapidly transformed into alcohol-like compounds, and finally into carbon dioxide and water; but up to the present time chemists have not been able to imitate plant life so thoroughly as to make these CHO elements combine either with free nitrogen or nitrogenous compounds and form proteid bodies.

By this careful study of the subject and of the tables illustrating the results that may be obtained by oxidizing fat, sugar, and starch, and even alcohol, we find that these bodies are all quickly transformed over into the final products, carbon dioxide and water, and that they do not, from the nature of the chemical laws governing their oxidation, tend to stop short of this complete result.

With regard to the proteid or CHNOS elements of the food-stuffs, we find the task of transforming them is much more difficult, and that they are very prone to stop short of the final and complete products of oxidation. Table VI. illustrates most perfectly a few of these abnormal results, such as the uric acid, oxalic acid, lactic acid, and the induction of the rheumatic state and the diabetic condition or diatheses, as they are sometimes designated.

The examples above given are only a few of many ab normal sequences which follow an interrupted or an abnormal metabolism of the proteid elements. These are cited because they are among the simplest deviations, and are pathological conditions familiar to every clinician.

The great reason for dividing our food stuffs into their fundamental classes is to avoid every source of error which otherwise would arise in the discussion of this important subject. To compare alcohol to a proteid is not in the least justifiable, as one is a nutritious and the other a non-nutritious and stimulating compound. Likewise, to compare alcohol to a given vegetable or to a cereal is only misleading, for in the former we are dealing with a simple

TABLE IV.—*Possible Products of Oxidation of the Proteids or CHNOS Food-stuffs.*

5. Oxalic acid		(0)	$129 = 2(CH_4N_2O)$ +	$2(C_5H_4N_4O_3)$ +	$2(C_4H_7N_3O)$ +	$7(C_2H_2O_4)$ +			$38(CO_2)$	+ $33(H_2O)$	+ H_2SO_4
6. Lactic acid		(0)	$124(0) = 2(CH_4N_2O)$ +	$2(C_5H_4N_4O_3)$ +	$2(C_4H_7N_3O)$ +		$2(C_3H_6O_3)$ +		$40(CO_2)$	+ $34(H_2O)$	+ H_2SO_4
7. Diabetic		(0)	$76(0) = 2(CH_4N_2O)$ +	$2(C_5H_4N_4O_3)$ +	$2(C_4H_7N_3O)$ +			$5(C_6H_{12}O_6)$ +	$22(CO_2)$	+ $10(H_2O)$	+ H_2SO_4

[1] Represented in the urine by a sulphate.

CHO element, but in the latter with a complex body composed of three similar, but distinct, CHO non-nutritious stimulating substances, and one purely nutritious or CHNOS compound element, which is capable when perfectly oxidized of being developed into all forms of bodily tissues and glandular structures. For these reasons it has seemed absolutely essential to resolve our food-stuffs into their component parts, and to first compare elements of like nature and then those of dissimilar composition, that the true position of alcohol may be clearly elucidated. Comparative deductions between a simple CHO element on the one side and a compound and complex CHNOS substance on the other, will of necessity yield absolutely different results—sequences which in a measure have no relation whatever to each other. For, as we have seen, one class furnishes tissue forming elements, while the other does not, but yields simply heat, energy, and rotundity, and acts as a lubricating agent.

Another thing of importance to be considered in this discussion of the physiological relation of food and alcohol, is the composition and comparative merits of the commonly admitted food-stuffs and their respective functions.

If we commence by an examination of milk, which is Nature's primary food-supply to the infant, we find that during the early stages of lactation, it contains more of the CHO elements, or fat and sugar, than it does of the CHNOS, or proteid compounds. This, however, is evidently one of the wise provisions of nature, for in this arrangement the milk supplies to the infant the elements for generating the heat and energy which the child in itself is not capable of producing by its own movements, or of developing out of the oxidation of the proteid compounds casein and serum albumin contained in the milk. At least not in sufficient quantities to keep up a perfect physiological condition; and even under the existing circumstances extraneous warmth must be added for the most complete development of the child. As the infant progresses and the period of lactation advances, the fat and sugars of the milk are decreased, which is equivalent to a rise in proteids so far as relative quantities are concerned. With the further growth of the child eggs should be added to the diet, as they furnish the next best food, simply because the percentage of the proteid elements exceeds that of the fats. Yet the latter or CHO substances are constantly supplied in quite large amounts in the eggs and in the milk, which is still to be freely used. The fats and sugars in this manner are supplied at all times in sufficient quantities, at least, to maintain the required bodily heat, energy, and lubrication.

With a little more advance in the development and appearance of the teeth, lean meat should be added to the diet. This by its preponderance in proteids will furnish a liberal supply of that much needed nitrogenous pabulum out of which the growing tissues and glandular structures can alone be formed. This egg and meat diet with the milk should be fully established before the first year of life is passed. The fat of the meat that cannot be isolated from the muscle-fibre, together with the sugar and fat of the milk, and the fat of the egg, will still supply an abundance, if not an excess, of the CHO compounds to yield all the heat, energy, and lubrication that is required aside from that which is generated in connection with the proteid transformation.

In some rare instances it may be wise or even necessary to add some of the starch and sugar substances, but as a rule this should not be attempted until the end of the first year or later.

The results which follow such a course of feeding are the growth and development of strong and robust children, and the formation of powerful adults having the maximum amount of vital force and resisting powers. We have children whose oxygenating capacity is not over taxed, and in whom the nervous mechanism is not continually hyperstimulated by this quick transformation of an over-abundance of the CHO elements. These fats, sugars, and starches, which are constantly being oxidized into alcoholic like compounds when taken in excess, yield an unduly large amount of heat and energy, usually at the expense of a perfect metabolism of the proteids or CHNOS class of food-stuffs. Consequently the above desirable conditions cannot be acquired if the CHO elements are allowed to preponderate, for the system is absolutely dependent upon a complete transformation of the proteids to obtain the highest type of development.

Another very potent reason for not using the CHO compounds in abundance at this early period of life is found in the fact that in the infant the pancreatic gland, which has for one of its functions the production of a starch transforming ferment, does not, under the most favorable circumstances, commence to secrete this agent, amylopsin, until near the end of the first year or well into the second year of existence, This ferment is the active principle by which most of the starch and sugar is finally transformed into a diffusable glucose, and when it is absent all starchy compounds that are introduced into the alimentary canal must remain undigested, and tend to undergo retrograde changes, excite digestive derangements, and interrupt the perfect metabolism of the proteid bodies, thus in another or indirect way enfeebling the system at large.

The quickness with which the pancreatic gland can be developed and empowered to produce this ferment will depend largely upon the early feeding and the nutritive tone of the infant. If the child is fed liberally upon the proteids, and the CHO elements are not pushed to excess at the expense of the former compounds, the development of the pancreatic gland and of all its ferment bodies will be established early, but if fed in an opposite manner the reverse can be expected. Still another reason for avoiding the sugars and starches during the infant period, and in fact throughout life, is that we have found them to be non-nutritious, stimulating compounds, which cannot be combined by the animal chemico-physiological powers with free nitrogen or with nitrogenous bodies to form the proteid protoplasmic elements, which are absolutely necessary in the construction of all the tissues and gland-structures.

The almost universal practice of using vegetables and cereals so largely, and often to the exclusion of the requisite quantity of milk, eggs, and meat, is the chief factor in devitalizing the human race, and stimulating a common and strong desire on the part of the human system for the more quickly acting alcoholic compounds. This false method of feeding is the foundation of most dyspeptic, rheumatic, and chronic diseased conditions. It is also the great cause of the large infant mortality, and the almost universal tendency to develop tuberculosis upon the slightest provocations.

This excessive use of the CHO compounds is the

prime agent in keeping down general longevity, which should be decidedly advanced by our present superior knowledge.

We find, by reference to Table VII., that for bare subsistence, equal quantities of the CHNOS and CHO food-stuffs will maintain an existence. When the work is increased, however, both kinds of food-stuffs must be raised in quantity to meet the demand, but the necessary rise in the proteids is very much greater than is the case with the fats, sugars, and starches.

TABLE VII.—*Comparative Diet Table.*

Diet.	CHNOS.	CHO.
Bare subsistence	100	100
Moderate exercise	180	161
Active labor	232	171
Forced work	242	189

With this information well in mind, if we look at the composition of our food-stuffs as given in Table I., and particularly at the vegetable list and the cereals, and compare them with meat and eggs, we find that although they do contain in most instances a large percentage of the proteids or CHNOS compounds, the preponderance of the CHO elements is still very great. Consequently it is absolutely impossible to use them with safety from bare subsistence up to an active or forced labor diet, to meet the physiological demands of the system, for the reason that to obtain the requisite percentage of the proteid elements necessitates the introduction of an enormous excess of the fats, sugars, and starches, particularly the latter. As a result of such an attempt the CHO compounds, which are most easily oxidized, are transformed first, with the production of an abnormally large quantity of heat and stimulation, which tends to exhaust the oxygenating capacity of the blood; and next the proteids, which, although introduced in the proper amounts, are nevertheless incompletely oxidized. The natural sequence is a system constantly overstimulated and in a state of intense physiological excitement, while all the tissues are becoming poorly nourished. This state of affairs is naturally followed in time by insomnia, hypochondriasis, neurasthenia, and a host of other mental and physical diseases of various names, until the unfortunate sufferers lose mental balance through this defective nutritive condition, and are driven in madness and despair to seek for relief in alcoholic stimulation, and often the latter end is worse than the first.

It becomes quite apparent, therefore, that there is a very general and strong tendency to carefully feed the human mechanism upon the non-nutritious and stimulating food-stuffs, to the exclusion of the proteid or nutritious class—either directly, or indirectly by crowding the proteids out with an over-indulgence in the fats, sugars, and starches—till finally, by force of necessity the system arrives at a point where alcohol alone will satisfy the demand for stimulation. Each additional dose or potion of alcohol introduced into the body leaves the animal economy more poorly nourished, more quickly and positively depressed, so soon as the exhilarating effects of the alcohol have passed off. With each succeeding draught and its consequent depression the demand on the part of the system becomes more and more urgent for restimulation, until finally the picture of the insane drunkard is presented to us. All the vital powers of the body are positively deteriorated, until both the physical and mental courage is reduced to such a low ebb that all chance for restoration and recovery is nearly destroyed. But, fortunately, and from the fact that alcohol *per se* has no poisonous properties, when the alcoholic supply is withdrawn and in its place is supplied a liberal allowance of the proteids or CHNOS compounds, the nutrition is quickly re established, the tone of the tissues improved, normal glandular activity induced, and the physiological functions, the physical and mental powers raised up to, or even carried above, the normal standard. When once this is accomplished the system is in a strong position to resist all damaging influences, and the individual can fight manfully and successfully the little desire that is left for alcohol and its stimulating effects.

If there is a return to an excessive use of alcohol, it invariably follows a period of over-work or an incomplete supply of the truly nutritive food-stuffs, or else it is on account of consummate moral depravity.

Unless the buoyancy of spirits developed from this stimulation by alcohol has been fully appreciated under these circumstances of intense depression, it is absolutely impossible to understand or realize what the sufferings are, or how strong the desire for relief becomes.

Neither can it be understood why the system returns so quickly to the alcohol. For such reasons as these, great sympathy should be extended to these unfortunate and half starved mortals.

The restoration in such instances commences at the bottom of the physiological foundation, and not alone at the apex of a moral peak.

When an opposite course of feeding is pursued up to manhood and on through life, an entirely different result will be obtained. If the infant and growing child is fed according to the laws of nature—and not by the rules of the "say sos"—upon a liberal nitrogenous diet with just enough of fat, sugar, and starch, or CHO elements to sustain the heat and energy of the body and at the same time allow a perfect oxidation of the proteids, or CHNOS compounds, a powerful physiological organism will be engendered which will place the individual in a position to abstain easily, not only from the use of alcohol, but also from all substances that will in any degree tend to undermine or weaken the moral and physical forces of his natural being.

Continued, or even vigorous, work does not leave the body in that exhausted and depressed condition that demands so strongly a powerful and quick stimulation to disperse the physical and mental lassitude. In the former examples this was developed to a degree of desperation, and with a desire that must be met at once regardless of the consequences that followed.

In properly-fed subjects, although they are often very much over-tired and even at times exhausted, the nitrogenous food-stuffs and natural sleep are generally found to be more than equal to the demands of the system, and alcoholic stimulation is not required or even desired. This is most perfectly and beautifully illustrated in the well-nourished child who, after the night's sleep and rest, always arises bright and early, brimful of life, vigor and activity, and full ready for another day of intense activity.

When the mental or physical powers, or even both, have been severely taxed and brought into a condition bordering upon extreme exhaustion, and when great depression of all the physiological functions is induced, alcohol, by being quickly absorbed and rapidly transformed within the system with its large yield of heat and energy, can often be used to great advantage on account of its mighty power to call temporarily into action all the reserve forces of the system. Under these circumstances alcohol alone is a very valuable adjunct to our dietary or medicinal list.

Whether alcohol is to be called a food-stuff or a drug naturally depends somewhat, if not entirely, upon the limitation of the term food-stuff. In connection with our present chemical and physiological knowledge in relation to the food-stuffs, and our present study of the subject, alcohol, more accurately speaking, belongs to the class of medicinal stimulants. Alcohol in these conditions, by its power to stimulate quickly and forcibly the nervous mechanism and call into action all the functions of the body at large, often enables the system to regain its normal physiological tone, when it could not accomplish this result by the aid of any or all the other known means of stimulation at our command. Thus by this most valuable influence of alcohol, many a life has been and can be

saved, that without its aid must of necessity have been sacrificed.

Tea and coffee act in a somewhat similar manner to alcohol. So do many other agents which contain nitrogenous and glucosidal principles. Caffeine and theine are of less utility as stimulants, because they are not so quick and forcible as alcohol, but they are also capable of serving the body as nutritive compounds. This statement holds true for most of the alkaloids. A few of the liquid alkaloids and volatile nitrogenous compounds, and some of the glucosides or CHO elements, are equally as rapid in their stimulating action as alcohol, but can only be used for a very short time, and then must be replaced by alcohol or the patient will die. This is due to their developing more rapidly than does alcohol poisonous compounds within the system when their use is prolonged.

Some of the alkaloidal principles in their transit through the body have a poisonous action, or develop toxic leucomaïnes or ptomaïnes by their presence within the system, and consequently cannot be administered in sufficiently large amounts to produce the desired effects as food elements. From the nitrogenous nature of their composition and the theoretical facts—as illustrated by Table VIII.—(showing that they can be oxidized into urea, carbon dioxide, and water), some of these alkaloids, like caffeine, can be utilized by the system not only as a stimulant, but also to serve the purpose of a nutritive compound for the support of the body-tissues and gland-structures.

Table VIII.—*Possible Products of Oxidation of the CHO, CHN, and CHNO Drugs.*

Drugs.		Amount of oxygen used		Urea		Carbon dioxide		Water
1. Alcohol	C_2H_6O	+ 6(O)	=	....	+	$2(CO_2)$	+	$3(H_2O)$
2. Digitoxin	Glucoside? .... $C_{31}H_{52}O_7$	+ 51(O)	=	.....	+	$21(CO_2)$	+	$16(H_2O)$
3. Digitalin	Glucoside..... $C_8H_{14}O_2$	+ 12(O)	=	.....	+	$5(CO_2)$	+	$4(H_2O)$
4. Digitalein	Glucoside..... $C_{26}H_{40}O_{13}$	+ 55(O)	=	.....	+	$25(CO_2)$	+	$20(H_2O)$
5. Digitonin	Glucoside..... $C_{31}H_{52}O_{17}$	+ 71(O)	=	.....	+	$31(CO_2)$	+	$26(H_2O)$
6. Convatlamarin	Glucoside..... $C_{23}H_{44}O_{11}$	+ 57(O)	=	.....	+	$23(CO_2)$	+	$22(H_2O)$
7. Strophantin	Glucoside..... $C_{29}H_{24}O_{11}$	+ 46(O)	=	.....	+	$20(CO_2)$	+	$17(H_2O)$
8. Sparteine	Liquid alkaloid. $C_{15}H_{26}N_2$	+ 40(O)	=	CH_4N_2O	+	$14(CO_2)$	+	$11(H_2O)$
9. Ammonia	Carbonate..... $2(N_2H_{10}C_2O_5)$			$3(CH_4N_2O)$	+	CO_2	+	$5(H_2O)$
10. Caffeine and theine	Alkaloid ..... $C_8H_{10}N_4O_2H_2O$	+ 13(O)	=	$2(CH_4N_2O)$	+	$6(CO_2)$	+	$2(H_2O)$
11. Strychnine	Alkaloid ..... $C_{21}H_{22}N_2O_2$	+ 47(O)	=	CH_4N_2O	+	$20(CO_2)$	+	$9(H_2O)$
12. Atropine	Alkaloid ..... $2(C_{17}H_{19}NO_3)$	+ 82(O)	=	CH_4N_2O	+	$33(CO_2)$	+	$18(H_2O)$
13. Morphine	Alkaloid ..... $2(C_{17}H_{22}NO_3)$	+ 85(O)	=	CH_4N_2O	+	$33(CO_2)$	+	$21(H_2O)$

Caffeine and some of the other alkaloids are less volatile and transient in their effects than alcohol, and furnish to the system nutriment while passing through the body, and consequently are not so liable to be carried to the dangerous excess so commonly witnessed when the various CHO elements are administered.

Although alcohol has this mighty power for good, it should always be regarded as a dangerous medicinal agent, and a substance never to be admitted to the common list of food-stuffs for daily consumption. It should never be taken by the young and middle-aged when in a fairly good physiological condition. Alcohol should never be introduced into the system except when positively diseased processes are present. At times, however, in connection with the weakening and retrograde states which are the necessary concomitants of advancing years, a little alcohol may be used daily with the ordinary food-stuffs to great advantage, to meet those deteriorating influences which are equivalent, so far as the physiological functions of the body are concerned, to pathological changes. Used at this age and under these limited circumstances, alcohol decidedly improves the general health and greatly prolongs human life and usefulness.

The chief reason why the ordinary individual in health should not use alcohol is, that he has no means for knowing the exact quantity that can be taken safely and still keep within the physiological limit, but is very much more likely to imbibe more than is reasonably required. When the use of alcohol is held rigidly within the physiological limit, as it should be if used at all with the other food stuffs, no perceptible effect will be directly experienced, but a gradual and daily improvement in the general condition will be the invariable result. If, however, the alcohol is once carried beyond the absolute physiological boundary line—which again is never stationary but constantly oscillating—it invariably leaves the system in a state of secondary exhaustion which is far greater and more depressing than the primary state which it was taken to relieve. This second sinking often leads to the false supposition that enough of the alcoholic stimulant was not ingested to meet the primary demand. More is imbibed, followed by an increased or second alcoholic depression far worse than the first, and so on repetition follows repetition, until finally the oxidation of the proteids is perceptibly impaired and the alcoholic habit almost irreparably established.

Viewed in this light alcohol becomes a food-stuff in the same manner as any of the CHO compounds, such as fat, sugar, or starch; but it is an element of high and dangerous potency, one that cannot be safely used by all, and for that reason alcohol should not be classed, nor introduced into the system, as one of the ordinary food-stuffs.

With this exact chemical and physiological knowledge upon this important subject, alcohol clearly belongs exclusively to the domain of medicine, and even there its use should be guarded by an ever-watchful care and its administration always kept strictly within the physiological boundary line. For in the combined elements C_2H_6O, which constitute the chemical composition of alcohol, we find consummate powers for good and equally mighty elements for damaging the human economy. By its use life can be saved or destroyed, depending entirely upon the skill of its administration.

The deductions which naturally arise from this study of the subject are:

1st. That three classes of proximate principles are necessary to maintain life, and must be supplied as food-stuffs.

2d. That the term food-stuff should be limited to those substances which contain at least one element from each of these three classes in its composition, viz., an inorganic, a CHO, and a CHNOS element.

3d. That the first act mechanically, the second as non-nutritive stimulants, and the third as true nutritive elements which enter into the essential construction of all the tissues and glands of the body.

4th. That the use of the second class or CHO compounds—including alcohol—when taken in excess of the absolute demands of nature, all tend to overtax the oxygenating capacity of the system and prevent a complete oxidation of the proteids or CHNOS bodies.

5th. That this continued over-stimulation and the half-starved condition arising through this excessive use of the CHO or non-nutritive and alcohol-forming compounds, tends most decidedly to weaken the vital forces, develop diseased conditions, and create the habit on the part of the system to take to alcoholic stimulation.

6th. That alcohol *per se* is no more poisonous than fat, sugar, and starch, but they are all factors in depriving the system of its full quota of oxygen to act upon the proteids, and from this incomplete transformation of the latter or CHNOS elements, nutrition is impaired and an almost unlimited number of toxic bodies produced.

7th. That alcohol and the chemical elements which enter into its atomic construction, and the transformation they undergo in passing through the system, and the final products eliminated from the body, are practically the same as follow upon the introduction of fat, sugar, and starch.

8th. That alcohol should only be classed as a medici-

nal agent, and never be used in health as a common article of food.

9th. That to combat most satisfactorily and successfully the alcoholic habit, the proteids or CHNOS food-elements should be the principal substances used, and the CHO compounds of all kinds should be avoided as much as possible.

10th. That there is a common tendency to feed improperly the animal economy from infancy to the grave, and to this false habit all the ills of the human race are largely traceable, and in it we find the chief factor in producing and maintaining the alcoholic habit.

AN EARLY DIAGNOSIS THE BEST TREATMENT IN POTT'S DISEASE OF THE SPINE.[1]

By V. P. GIBNEY, M.D.,
New York.

Mr. President and Gentlemen of the Association: The selection of a title which will prove of interest to practitioners in general is not an easy task. An experience with deformities extending over a period of twenty years prompts me to plead, wherever an opportunity offers, for early diagnosis.

At the Hospital for the Ruptured and Crippled and at my clinic, and even at my office, one would be amazed if he knew how many cases of Pott's disease of the spine come for treatment after the existence of deformity. The average practitioner seems to think that one must not think of making a diagnosis until deformity has arisen. When pressed for an opinion, he says: "Wait a while till we see how it is going to develop." He discourages the use of apparatus, talks about people being brace-ridden or bed ridden, and prefers to wait until the disease has made irremediable progress. The recognition of the disease before any deformity arises is not difficult, provided the physician has accustomed himself to making a thorough examination. The train of symptoms that belong to the early stages of Pott's disease is unmistakable when taken collectively.

For all practical purposes it may be assumed that recession of the bosse in Pott's disease never takes place. I use the terms "for all practical purposes" advisedly. I am aware that Dr. Taylor, of New York, has reported cases wherein recession has taken place, and I am perfectly willing to accept the report of his case. Still, the rule is that orthopedic surgeons do not obtain this result. Our only hope for the patient is our ability to make a diagnosis before any bosse appears. This diagnosis should be made before even a spinous process projects out of the normal line.

For ten or fifteen years of my professional life I worked daily with what is known as the Knight spinal brace. This consisted of a framework of steel which gave lateral and antero-posterior support to the spine, secured to the body by means of a canvas lacing in front. I can recall many instances now, and the hospital records, indeed, are full of extraordinary cases subjected to this method of treatment. There are many on record wherein no deformity was permitted. We got a case early, before deformity presented, adhered religiously to the apparatus, saw that it fitted well, persisted in the prolonged use of the same, and the results were indeed gratifying. Then again, I had a pretty long experience with the plaster-of-Paris jacket. When Dr. Vance, of Louisville, was associated with me at the hospital, many years ago, we used the Vance paper brace, made of manilla paper and glue. For at least four or five years I have used in private practice what is known as the Taylor spinal assistant, or, the Taylor spinal brace. By observation simply, I am more or less familiar with the effects of the woven wire corset. The rawhide and the felt jackets have also come under my observation, and I feel no hesitation in giving my opinion any time about any special form of apparatus. I have often heard surgeons who had invented an apparatus, or who had not had a very extensive experience, make the statement that with this or that apparatus deformity in any part of the spinal column could be prevented. I have heard these same gentlemen, years afterward, when questioned closely about the prevention of deformity, admit that if the disease appeared between the last cervical and seventh or eighth dorsal vertebra, it was next to impossible to prevent deformity. Recumbency in bed, with traction at the head and counter-traction at pelvis, with sand-bags on either side of the neck, has failed, in my experience, to prevent a certain amount of deformity in this region. For the purpose of illustration I should like to present for your consideration a few cases.

Case I.—A boy, five years of age, came under my care on February 6, 1888. A diagnosis was made of ostitis of the cervical vertebræ with abscess in right cervical triangle, anteriorly. He had been under the care of a distinguished surgeon, a veteran in orthopedic work, for at least a year and a half. The symptoms had been dropping of the head with chin toward sternum, occasional pain in the occipital region, but no bony deformity. Then the abscess appeared, and this was regarded as glandular. He was never really put under any critical examination. I found a certain amount of spasm of the muscles about the neck, especially those in front; rotators offered a little resistance. As he bent his head forward there was a slight amount of bony fulness of the transverse processes in the cervical region, but none over the spinous processes. The mother reported that for the last year, even, he had shown a disposition to rest on his elbows and was fond of lying down. I advised an apparatus with a jury-mast, or head-support, and also the opening of the abscess. It was a month before they permitted the operation to be done. On making incision, I found a small piece of bone which had evidently come from the body of the vertebræ. The cavity was well exposed, thoroughly cleansed, and after six or eight months it finally closed He wore the apparatus with head-spring faithfully night and day, and on July 14, 1890, I made a note that his spine was perfectly straight — no deformity whatever. Sinus was closed. The mother reported that sometimes it opened. The appliance still retained for the sake of protection. September, 1890, the apparatus was removed. Functions of the head apparently perfect. October 23, 1890, discharged cured. I had an opportunity of making an observation on January 23, 1891. There was still no deformity, and I am satisfied that a perfect result has been obtained.

Case II.—On November 4, 1886, a girl, five years of age, was referred to me by my friend Dr. George L. Peabody, of New York. She walked like an aged woman, bent over. Had been complaining since the August preceding. Occasionally she cried with pain. Had great distress about the epigastrium, and was disposed to keep the right thigh flexed on pelvis. The present exacerbation was only of a month's duration—came on after a strain. She was treated for gastric distress by her family physician, not Dr. Peabody.

I found it impossible to straighten her by suspension, yet there was considerable spasm of the psoas and iliacus muscles. Deep exploration of the iliac fossa failed to detect any abscess. I applied a plaster of Paris jacket. November 17th, a note was made that a spinous process projected, but otherwise she was straight. The plaster failed to give the desired support, and in May, 1887, I applied a Taylor brace. On June 2d I discovered a deep psoas abscess, and on June 10th I made deep pressure over the abdominal walls, got the walls in pretty close contact with the tumor, thrust a needle quickly through into the tumor, and removed about a half ounce of pus with the aspirator. On June 20th I repeated the operation under ether; again on the 27th. This time there was very little. I went abroad that summer, and

[1] Read before the Canadian Medical Association, at Montreal, September 16, 1891.

on my return, on September 15th, she walked perfectly erect, showing no lameness whatever. I could not detect any sign of the abscess. It was cured. From time to time I have made notes of the case. On October 10, 1887, I reported her in a paper on the "Management of Abscesses in Connection with Bone Disease." My last note was made November 4, 1890. "Hip functions perfect; limbs equal in length; no deformity of the spine; general health excellent; cure complete."

CASE III.—On December 30, 1889, Dr. Vander Veer, of Albany, placed under my care a lady, thirty-two years of age, who gave the following history: Three years before this, while riding horseback, she was considerably jolted, had pain at once, and was lame for several weeks after this. The pain then wore off apparently, and the following winter, while in Jacksonville, Fla., she had the same pain under the same circumstances.

She presented a very slight bosse, or kyphosis, in the dorso-lumbar region, extending from the sixth or seventh dorsal down to the sacral, the apex of the bosse being about the twelfth dorsal. There was a lateral deviation as well. The outline of the deformity was very unlike that of Pott's disease, and but for the presence of a fluctuating tumor just above the crest of the ilium, right side, in the ilio-costal space, I should have hesitated somewhat in making the diagnosis. The lady was the mother of a family, well developed, well nourished. The pain had been rather persistent. A needle soon detected pus in this tumor. I began treatment at once, employing for her a Taylor brace. The abscess was aspirated by Dr. Vander Veer. She suffered a good deal of inconvenience during the month following the adjustment of the apparatus, because I had not had a fair opportunity of fitting it. As soon as it was made comfortable she had no further trouble with her back. I think she had, during the following spring, two or three aspirations, and during the remainder of the year there was nothing of any special interest in the case other than a general progress toward recovery. On February 3, 1891, I found it difficult to detect even the sac of the abscess. She had worn the brace continuously, night and day, there was no spinal tenderness, the deformity had not increased. In March of present year, 1891, I replaced the steel brace with a corset heavily boned, and on May 11th she reported that she felt almost as well as ever she did. In other words, I discharged the case as cured, with the caution that she must wear this heavily-boned corset and avoid any unnecessary jar or concussion in the future.

CASE IV.—The following case is of interest because of certain difficulties in diagnosis: A robust man, thirty-two years of age, was referred to me on March 10, 1891, by Dr. MacCreery, of New York, with a history that two weeks prior to this date he was injured in a railroad accident. He fell backward, striking his loin against an iron casting. Three or four hours afterward he had to give up walking, but next day was going about, still complaining of this bruised feeling. There was a little irregularity of the spinous processes of the last dorsal and first, second, and third lumbar. He was exquisitely sensitive. The erector spinæ muscles on the left side were more prominent than those on right. If he held himself erect, this irregularity did not disappear. I could find nothing in the iliac fossa except superficial tenderness. The thighs were moved quite freely without resistance, so that I made a diagnosis of simple contusion and advised rest and the Paquelin cautery. On May 15th Dr. MacCreery asked me to see him again, because of continued pain in his back and of his increased awkwardness of gait. The doctor had applied a plaster-of-Paris jacket, but the patient had cut it out in places, and hence it was no longer efficient. I found, now, tenderness on concussion, no angular deformity, but pains in the epigastrium and down the thighs. The spinal column was very sensitive to pressure. The spinous processes of the eighth and ninth dorsal vertebræ seemed a little more prominent than those immediately above and below. This little fulness could be detected only by very close examination. I put him quite straight in the swing, applied a plaster-of-Paris jacket, made it into a corset, and began treating him with the Paquelin cautery once or twice a week. I have not allowed the jacket to be removed, except when he is in the swing partially suspended. Then I take it off, have his back washed, apply the cautery, put on a clean undervest, and lace up the jacket snugly before he leaves the swing. In this way he is making material progress. One or two physicians have examined him, but failed to see any signs of Pott's disease, remarking that it is best to wait until we see deformity.

The cases just reported illustrate, I think, the necessity of close examinations, and of giving the patient the benefit of whatever doubt may exist. If one finds a history of trauma in an adult, and this trauma followed by pains of a vague nature, pains that follow certain nerves, these signs should command very close attention. It must be remembered that spinal tenderness is the rule in adult life, the exception in childhood. The average physician is sufficiently well-informed in anatomy and physiology to interpret pains and muscular spasm; the average physician can easily recognize deviations from the natural form, and the only reason why correct diagnoses are not more frequently made is that the average physician doesn't strip the patient and subject him to a critical examination. If my paper, thus hastily put together, impresses a certain number of my hearers with the importance of a routine examination, then my object will have been attained. Remember that the successful treatment does not depend so much on the apparatus employed as on a careful diagnosis. Anyone, I am sure, who can diagnosticate this lesion will have become sufficiently familiar with the clinical history and the pathology to appreciate the value of prolonged immobilization and rest to the parts diseased.

ON DERMATOL, A PROPOSED SUBSTITUTE FOR IODOFORM—ITS USE IN SURGICAL PRACTICE.

BY CHARLES A. POWERS, M.D.,

SURGEON TO OUT-PATIENT DEPARTMENT, NEW YORK HOSPITAL.

IN June of the present year Heinz and Liebrecht[1] commended to the profession, for use as an antiseptic powder, a basic gallate of bismuth to which they gave the name "Dermatol."

The remedy is a yellow, fine powder, unaffected by exposure to light and air, and non-hygroscopic. It had been the subject of extensive experimental and clinical investigation at the university in Breslau, having been used in surgical, gynecological, and dermatological practice. It was found to influence the healing process in wounds, ulcers, and the like in a markedly favorable manner, and was thought to combine the better properties of iodoform with the decided advantages of being without odor, non-poisonous, and non-irritating. It was recommended for use in all dressings in which we are accustomed to employ iodoform.

In a further communication Heinz[2] gives in detail the causes which led to the experimentation and the manner in which it was conducted. He says, with truth, that an antiseptic should not only be able to kill germs or restrain their growth, but that it should also be free from injurious local or general effect. It should not cauterize or irritate the wound or its surroundings.

Of the dry antiseptics, iodoform alone has thus far been able to prove itself of exceptional value, and to win for itself a permanent place in surgical practice.[3]

[1] Berliner klinische Wochenschrift, 1891, No. 24.

[2] Ueber das Dermatol, Berliner klinische Wochenschrift, 1891, No. 30.

[3] An exceptionally clear and complete paper on the Present Status of the Iodoform Question, by Dr. W. W. Van Arsdale, appeared in the Annals of Surgery for 1889 (vol. ix., p. 202). I judge the present views to differ but little from those expressed in this résumé.

The disadvantageous qualities of iodoform, however, are only too well known. Most prominent among them is its poisonous effect,[1] and it is never quite possible to estimate personal idiosyncrasy and susceptibility when using the drug. This alone makes it most desirable to seek a substitute, and in a search for something which would replace iodoform Heinz and Liebrecht experimented with various of the iodine-holding compounds (Iodacetanilid, Iodsalicylsaüreanilid, etc.), many of the phenols, pyrogallic acid, chrysarobin, hydroxylamin, phenylhydrazin, and a large number of other substances, all without satisfactory result. Gallic acid commended itself as a non-poisonous, reducing agent, and as a metal with which to combine this acid bismuth was selected because of the astringent and "drying" effects which its inorganic salts have shown.[2]

The basic gallate of bismuth proved itself to be a non-irritating, non-poisonous drug, while it seemed to possess the better qualities of the subnitrate of bismuth in a marked degree.

Large doses were given to dogs and rabbits, considerable amounts were introduced beneath the skin and in the peritoneal cavity, all without poisonous effect.[3]

Experiments were made regarding its antiseptic properties, and it was found that when the dermatol was added to a fluid nutrient gelatine, decomposition or bacterial growth was hardly hindered. The same occurs with iodoform, iodol, bismuth-subnitrate, and aristol. The dermatol can take effect only when it comes in direct contact with the germs, and when it is evenly mixed with the nutrient medium. This they accomplished in the following manner:

Gelatine was warmed in a reagent glass until it was just fluid (28° to 30° C.), and with it large amounts of dermatol were mixed. This was then mixed with a pure culture, shaken, and poured on cooled trays. As it stiffened in cooling the dermatol was held in a uniform admixture. The anthrax bacillus, staphylococcus pyogenes aureus, bacillus prodigiosus, bacilli of typhus and of pneumonia, were used. In all of these the growth was stopped.

In the further proving a considerable amount of the dermatol, mixed with a culture of staphylococcus pyogenes aureus, was introduced beneath the skin of a dog or rabbit. As a "control," another culture of some indifferent powder—starch or talc—was similarly introduced beneath the skin of a similar animal. In the latter a more or less extensive abscess appeared within twenty-four hours, while in the animal in which the dermatol was used the skin wound remained absolutely dry and not the least suppuration occurred. When the abscess produced by the staphylococcus culture was opened, washed out with a one-tenth per cent. sublimate solution, and dusted with dermatol, the suppuration ceased, the wound filled with granulations, and was healed in an exceptionally short space of time. The unusually dry condition of wound surfaces, abscess walls, etc., is of importance in that it decreases the fluid media essential to bacterial growth.

Rosenthal[4] seems to confirm the experiments of Heinz. He finds that bacterial growth remains absent when the dermatol is present in large quantity, but that otherwise the results are negative.[5]

With a view to corroborating the above I sent some of the powder to Dr. F. Ferguson, pathologist to the New York Hospital, who returns to me the following report:

"I have experimented with the powder 'dermatol,' which you sent to the laboratory of the New York Hospital, and find that growth of bacteria did not result in any of several tubes of agar and gelatine inoculated with the powder. I found that bacteria of different kinds, pathogenic and non-pathogenic, could be left in contact with the powder as long as twenty-four hours, and again grow when transferred to agar. I found that on mixing equal volumes of dermatol and agar, bacteria grew upon the surface of the mixture, but not as actively as when smaller quantities of powder were used in the mixture."

Rosenthal, however, reports that his positive results were obtained only when he pursued a special course (see original), and it may be that difference in methods leads to this divergence in results. However that may be, we cannot assume that the germicidal properties of the drug are active, and it is not to be thought that it can take the place of our standard irrigating fluids. It is, nevertheless, possible that, as in the case of iodoform, clinical evidence will rate the drug more highly as an antiseptic than would seem warranted by bacteriological experimentation.

In clinical use the reports of a certain number of observers lie before us:

Sackur[1] used dermatol in a series of about one hundred cases in which he would ordinarily use iodoform. These embraced fresh wounds of all kinds, operative and traumatic, ulcers, opened abscesses, fistulæ, etc. In fresh wounds the course ran smoothly. When union was not attempted the surface was covered with epithelium under a dry scab. In sutured wounds the dressing "fell off dry." All fresh wounds healed without reaction, fever, or suppuration. Burns healed very quickly. In non-aseptic wounds, abscesses, etc., the secretion rapidly diminished, nevertheless he could not dispense with moist antiseptic dressings.

In all cases the drug checked the secretion to an astonishing degree, and it rapidly cured the eczema caused by carbolic and bichloride dressings. Large superficial leg ulcers, which had for weeks and months resisted the ordinary forms of treatment, grew rapidly smaller and closed under the dermatol. A considerable amount of the powder, however, seemed necessary, and it was not useful in torpid ulcers which required stimulation. In no case was eczema occasioned.

Glaeser[2] reports on his use of the drug in the clinic for women at Breslau. He employed it in small wounds as well as in those leaving great defects, in perineal and intra-uterine operations, total hysterectomies, etc. It led to quick healing without irritation.

In a case of extra-uterine gestation in which the mass could not be removed, as well as in a very large tubercular peritoneal abscess, he used it in large quantities for weeks without poisonous effect.

He found it less efficacious in the infectious catarrhs of the genital tract, and thinks it of questionable value in tubercular processes.

Rosenthal (loc. cit.) used the dermatol, in his dermatological practice, dry, or in the form of salve or paste, in ulcers of various forms, bubo wounds, balanitis with much secretion, suppurative lymphangitis of the penis, eczema—especially the wet form—and other affections, and expresses himself as greatly pleased with the powder, saying that he thinks that it will find wide employment in dermatological practice. After its use as an injection in a few cases of gonorrhœa, he thinks the results sufficiently encouraging to warrant extended trial.

Von Rogner[3] thinks it "the best dry antiseptic of the day." He has used it in extensive burns of the trunk, and has never observed stomatitis, darkness of the mucous membranes, intestinal catarrh, or other constitutional effects.

During the past two months dermatol has been used in my surgical class at the out-patient department of the New York Hospital in upward of one hundred and fifty cases.[4]

[1] I have very recently learned of two deaths, in the larger hospitals of this city, during the past summer, attributed to iodoform.
[2] For full text see the original article.
[3] This property of being non-poisonous is attributed to its insolubility and permanency.
[4] Berliner klinische Wochenschrift, 1891, No. 29.
[5] He obtained practically the same results with subnitrate of bismuth and aristol.

[3] Wiener Medizinische Presse, August 16, 1891, No. 33.
[4] Not all, however, were followed to ultimate result.

These embrace fresh wounds of all varieties, ulcers, abscesses, burns, and the like, all cases, in fact, in which iodoform is generally employed. It has been used as a dusting powder, sprinkled on in thicker or thinner layers. Until recently I have been unable to obtain a sufficient amount of the drug for use in gauze.

I have thus far been exceedingly pleased with its effect. Fresh wounds were cleansed with a sublimate solution of the powder applied beneath a dry or moist dressing. In no case did sepsis occur, and the wounds healed, so far as I have been able to judge, in about the usual length of time. Chronic ulcers, especially those of the leg and foot, closed with exceptional rapidity.

Many of these troublesome cases which had shown but little progress under the ordinary dressings, healed astonishingly fast.

The characteristic decrease in the secretion, spoken of by all authors, has been very noticeable. Surrounding eczema disappeared under one, two, or three dressings. In no case did the drug cause irritation, in no case was the slightest poisonous effect noticed, even when considerable quantities of the dermatol were employed.

In some cases opportunity was offered to compare its effects with those of iodoform. So, for example, in a man with extensive, symmetrical, specific ulcers on the anterior aspect of each leg. On one leg dermatol was used, while iodoform was applied to its fellow.[1]

The ulcers on the leg on which dermatol was employed were healed in less than one-third the time required by those on the extremity subjected to iodoform.

In a patient with burns of the second and third degrees, one portion was treated with dermatol, another with iodoform. Here, again, the new drug showed its superiority.

A man, aged forty, had suffered amputation of the ring-finger at the hands of surgeons outside the dispensary, the wound being dressed in the ordinary way with iodoform and bichloride. He presented himself at my clinic five or six days after the operation, with hand and fingers much swollen, puffy, œdematous, red, from wrist to finger-tips the seat of a profusely weeping eczema. The amputation wound was in perfect condition—it had healed *per primam*, and I was told by the surgeon who did the operation that the eczema was occasioned by the dressing. All affected skin was covered with a fairly thick layer of dermatol, over which plain, unmedicated gauze was applied. At the first change of dressing, on the third day, the parts were dry, painless, practically healed.

Such simple granulating ulcers as those left after Cotting's operation for ingrown nail, healed with exceptional rapidity. On the other hand, I have not found tubercular ulcers to make more than ordinary progress under its use, while it does not seem suited to the torpid mucous ulcers which are deficient in secretion, or to those with exuberant, flabby granulations. In a word, a surface must be in a fairly healthy, granulating condition, and when it does present this the dermatol effects healing in a remarkably short space of time.

Phlegmons, abscesses, carbuncles, and the like must be cleared of slonghing tissue before reliance is placed on the dermatol.

When compared with iodoform, it certainly possesses qualities of exceptional merit. Its lack of odor, and its absolute freedom from poisonous and irritating effects are most valuable features.

It is, of course, more than possible that further use may demonstrate disadvantageous qualities, or curtail the favorable characteristics which have been mentioned. It is to be hoped that in time we shall have presented to us an agent which more nearly approaches the ideal. In regard to this drug dermatol, however, all of the written opinions which I have been able to find are singularly enthusiastic in its praise, and these are sufficient to demand for it an extended trial. I am using it, at present, in my out-patient surgical cases, to the exclusion of iodoform, in all dressings in which that drug was formerly employed, as a powder, in a ten per cent. gauze, in a ten per cent. ointment with vaseline, and in a ten per cent. collodion emulsion, and thus far I have all reason for being satisfied with its effect.

I append a brief comparison between dermatol and iodoform.

a. CONDITIONS IN WHICH DERMATOL POSSESSES ADVANTAGES OVER IODOFORM.

Dermatol.	*Iodoform.*
1. It is not poisonous.	1. It is distinctly poisonous.
2. It is without odor.	2. Its odor is exceedingly disagreeable.
3. It is absolutely non-irritating, it allays irritation.	3. It produces, in many instances, a troublesome dermatitis of the surrounding skin.
4. It can be sterilized by dry or moist heat (this may be of distinct advantage when gauze is employed).	4. This is not the case with iodoform.
5. It seems, at present, to lessen discharge to a greater extent, and to favor epithelial formation to a greater degree than does iodoform.	

b. CONDITIONS IN WHICH IODOFORM[1] POSSESSES ADVANTAGES OVER DERMATOL.

Dermatol.	*Iodoform.*
	1. It is at present somewhat cheaper.
2. There is no reason for believing that it possesses direct effect on tubercular processes.	2. Its anti-tubercular action seems to be (clinically) fairly well established.
3. It is insoluble.	3. It is soluble in alcohol, and in ether.

35 WEST THIRTY-FIFTH STREET

[1] I postpone comparison of their germicidal properties.

RECENT MEDICAL JURISPRUDENCE.

BY HENRY A. RILEY, ESQ.,

NEW YORK.

Some New Features in Life Insurance.—Considerable attention is being attracted to insurance matters now, on account of the large defalcation in the Spanish Department of the New York Life Insurance Company, amounting to about four hundred thousand dollars it is claimed. As life insurance is pre-eminently an American institution, having received its greatest development in this country, anything which affects its stability is of general interest. It is stated that about a million and a half of policies are outstanding, insuring probably a million persons, for almost three thousand five hundred millions of dollars.

In about a generation this immense sum will be distributed among some millions of beneficiaries, should the companies continue to be solvent. The business has been very successful and profitable thus far, but there seem to be signs that the future will not see the wonderful expansion which the past twenty five years has witnessed. One of the great features of the system is the very large commissions which are allowed to agents for securing business, and it seems probable that a more conservative system of management will require considerable cutting in this item of expense. Another very remarkable suggestion has recently been made, and that is, the abolition of medical examinations entirely. This is a most radical change, and yet it is said that some of the English companies are contemplating such action. It is claimed by them that the mortality tables are based on the experience of one hundred thousand lives, and that the advantage of selection runs out in about five years, and that after that time the insured are no better physically than the same number of persons picked up at random in the streets. There will, no doubt, be a full discussion of this matter before its adoption, and probably few of the companies will feel like abolishing medi

cal examinations, even if there should be quite a saving for the time being in medical fees. It seems quite evident, if the medical examiner was deposed, that there would be a general rush of the maimed, the halt, and the diseased to the offices of the companies for the purpose of taking out policies. This would bring a temporary increase of premiums, but most probably would so swell the death payments in a few years that the solvency of even the best companies would be threatened.

It will require very strong proof to show that the average of vitality is preserved when there is no discrimination shown to healthy persons over unhealthy ones at the time of application.

The whole subject of life insurance is so important and so complex that there should be nothing done to endanger popular confidence in the system.

Doctors as Politicians.—The recent legislation in a number of States, which seems likely to elevate the medical profession by requiring a higher grade of knowledge on the part of applicants for licenses to practise, has had the effect of calling to the attention of Maryland practitioners the fact that there is no license law on the statute-book in that State.

The *Maryland Medical Journal* believes in taking time by the forelock, and urges the infusion of medical politics into the caldron which is now beginning to seethe with Republican, Democratic, and Alliance ingredients. It calls upon the profession to insist on the election of a good number of physicians as members of the General Assembly, in order that a proper medical license law may be enacted. It would be well for everyone interested to watch the workings of the New York law, which seems a fair one, and which went into operation in September.

Convict Leases and Prison Management.—There have recently been a number of things calculated to call attention to prison management, and one of the most noticeable is the outbreak against the convict labor system in Tennessee. In this, as in some of the other Southern States, the convicts are leased out to the highest bidder, and are thus made to bring a revenue to the State, although the system is a cruel one and results in a very heavy death-rate. The enormities of convict leases were graphically told by George W. Cable, some little time since, with the result of making him cordially disliked in many parts of the South.

The trouble now is not caused by any sympathy with the convicts, but is the result of the antagonism of free laborers in the Tennessee coal mines, who object to being brought into competition with the convict labor at some of the mines. The revolt was so serious that troops were sent to the scene to preserve order, and bloodshed was only avoided by the promise that legislation would be secured to meet the wishes of the free laborers. In this State charges have been made in the daily papers of gross cruelty in the punishment of prisoners at the Clinton State Prison. The charges are direct and circumstantial, and deserve a careful investigation, although the Superintendent of the State Prisons is reported to consider them beneath consideration.

It has been said, also, that the manufacture of shirts at the Clinton Prison has seriously interfered with the business outside, and the number of convicts employed in this way has been largely reduced.

Suits against the City of New York.—Suits have been brought by Dr. Allan McLane Hamilton and Dr. Rudolph A. Witthaus, against the City of New York, for medical services rendered in the post-mortem examinations of the victims of the Fourth Avenue tunnel disaster. The examinations were made by order of Judge Patterson of the Supreme Court. The amount claimed was $500 in each case, which sum was allowed, but payment refused because there was no fund from which it could be taken. If judgment is recovered, as will naturally be the case, the claims can then be paid out of the judgment fund. Dr. Witthaus recently obtained a judgment of $750 against the city for chemically examining the viscera of Bernard O'Grady, whose death it was suspected had been brought about by poisoning.

Police Matrons.—The Board of Police of this city has shown a strange lack of appreciation of the good points of the law requiring matrons at the police-stations, and the Commissioners have had to be forced into taking action. The latest quibble has been a difference of opinion as to the salary to be paid, and for a time it seemed as if the matter would be indefinitely shelved. An agreement has, however, been arrived at to pay $720 per annum; but the matrons cannot be placed in charge until certain changes have been made in the station-houses. The money for this will not be available until the Board of Estimate and Apportionment makes an appropriation, and this may not be for some time.

One of the so-called health edicts relating to the importation of food products from this country was the prohibition of pork in France. This has now been removed, to the great joy of hog-raisers throughout the country, largely through the efforts of the American Minister, Whitelaw Reid. It is expected that the similar prohibition in Germany will soon be removed.

RADICAL CHANGE IN THE APPLICATION OF KOCH'S LYMPH, ATTENDED BY MARKED SUCCESS—FEVER REACTIONS PREVENTED

By FRANK FREMONT-SMITH, M.D.,

ST. AUGUSTINE, FLA.

The results of careful study of pulmonary tuberculosis in all stages, under prolonged treatment with tuberculin, lead me to state the following conclusions: 1. The dose of tuberculin is a widely varying quantity, to be determined, with its rate of increase for each case, only by direct experiment. 2. The only therapeutic dose is such a quantity as arouses no reactive temperature, every reactive fever being the expression of an overdose, that is, a poisonous dose. 3. Tuberculin, when successful by fever reactive method, is so despite, not by virtue of, reactions. 4. Tuberculin by non-reactive method acts as a powerful up-building alterative to the tuberculous subject. 5. Cases in all stages of tuberculosis may be treated by non-reactive method without danger.

Observation of numerous cases in Berlin, and especially a study of those in the wards of Leyden, Charité, to which free access was granted me at all hours, led me to conclude, first, that when treated with tuberculin, some cases, though in proportion few, made a definite and continued improvement in general physical conditions, in character of cough and amount of expectoration; second, that weak men and nearly all women progressed untavorably. Those cases which ultimately gained lost weight during the first week or two weeks of treatment. Such cases were usually men of great native vigor. Of women, who are especially susceptible to tuberculin-induced fevers, among fifty cases but one was improving in the wards of Senator; nearly the whole number were rapidly fading away, their reactive fevers tending to become continuous as treatment progressed. At Friedrichshain, the one hundred charts examined showed that no women with pulmonary forms were improving. Similar results were obtained in the wards of Gerhardt and von Bergmann, and at Moabit Hospital the successful cases shown were men. Among all these cases earlier stages of the disease were numerically well represented, but the induced fevers were exhausting and ruinous to all alike.

Of the disturbing or dangerous effects upon the local lesion, I spoke in my Berlin communication to the Medical Record of January 3d.

Although small doses have been mentioned by various writers, they have been employed with the full purpose of obtaining fever reactions, and have been increased

until these were achieved. American observers who have been unsuccessful and have discontinued the treatment, have invariably stated that characteristic reactions were obtained.

The entire absence of uniformity in results with incipient cases in the hands of all operators, and the uncertainty manifested by all as to the class among incipient cases in which success might be expected, suggested a possible error, not in the constitution of the remedy, but in its method of administration, which hitherto has not been adapted to obtain the fullest therapeutic effects with the least expenditure of energy. To produce every second day the ultra-physiological action of tuberculin, as exhibited in fever reactions, disturbs the general equilibrium and disarranges nervous, digestive, and secretory functions, upon whose very quietude and uninterrupted activity, substantial improvement is of necessity based. To employ any medicinal agent on a plan so irrational as that on which Koch's lymph has been used, would condemn our most powerful and valuable drugs, and, as in the case of tuberculin, soon discourage both patient and physician.

Since the proportion of improved cases in foreign and American hospitals was too small, the risk of the venture under the usual methods too great, I determined at the commencement of experiments at Alicia Hospital, St. Augustine, on January 27th, to adopt a plan, not as I am aware until the present time suggested by any observer; namely, to maintain the doses of tuberculin uniformly below the fever reaction line, proposing to employ such increasing dosage as may be borne by each individual without fever, its pain, mental depression, loss of appetite, and wasting of flesh; thus, perhaps, to escape renewed congestions in the diseased lung areas, and especially to retain general conditions for the patient as favorable, at least, as previous to treatment. Results of this plan are shown in the following notes of all cases treated at Alicia Hospital, taken from the records of this institution.

Incipient and advanced cases have been treated. I have endeavored in every instance, although gradually increasing the dose, to retain normal temperature. Women and delicate men in any stage are especially susceptible to the tuberculin fevers, hence the dose has been adapted to their condition. Individuals in apparently the same stage and physical state vary greatly in their resistance to induced fevers. The decided influence which this remedy has exerted in my hands under the gentle, steady pressure of non-reactive doses, has been analogous to that of the iodides—an alterative of well-established power.

Incipient Cases.—Case I.—F——, aged thirty-three; residence, Georgia; one brother and one sister died of tuberculosis; failing for the past six months. On entrance, feeble strength, poor appetite, harassing cough day and night; evening temperature, 99.6° F. to 100° F.; sputum, four ounces daily; bacilli numerous; infiltration of left lung apex down to third rib; moist râles; right apex, slight supra-clavicular dulness. First inoculation, January 27th, one-half milligr.; reactive fevers avoided until the twenty-ninth injection, dose 45 milligr., unexpectedly produced 101.2° F.; the dose was now modified and again gradually increased without reactions until, on April 24th, 85 milligr. were administered. Examination, April 23d, dulness persists; râles are absent; cough slight, none during the night; sputum one to three drachms daily; normal weight, 160 pounds; entrance weight, 136; weight, April 23d, 153; gain, 17 pounds.

Case II.—T——, aged twenty-three; residence in Florida, six years; mother and one brother, twenty-one years of age, died of tuberculosis; coughed for one year; hæmoptysis in January last; unable to work during the past seven months; evening temperature on entrance varying from 99.4° F. to 100.4° F.; night-sweats; area bounded by second and seventh ribs, right side, presents dulness; bronchial breathing, moist râles; bacilli, moderate numbers. First inoculation, February 17th, 1 milligr. During the first eighteen days of treatment maximum temperature was 99.6° F.; for the following fifty-three days the temperature reached 99° F. but five times, its maximum then being 99.3° F.; final dose, April 24th, 60 milligr.; thirty-three treatments administered; sputum on entrance, one ounce daily; after April 9th it never exceeded 4 drachms; weight, February 17th, 144 pounds; weight, April 23d, 164 pounds; râles lessened, otherwise physical conditions unchanged; cod-liver oil, which had been taken for months previous, was continued. Reported by Miss A. Smith, hospital superintendent, June 24th, "Improved after your departure; left hospital in May feeling well." Gain, 20 pounds.

Case III.—Mrs. C——, aged forty-one; residence, Florida; only sister died of tuberculosis, which exists on father's and mother's side; cough began early in October, 1890; dulness on the right side down to the fourth rib; bronchial breathing and râles; left side, slight dulness, supra clavicular bronchial breathing; bacilli in moderate numbers; during ten days of observation before inoculations began, evening temperature ranged between 99.5° F. and 100.2° F.; during these ten days weight fell from 127½ to 125 pounds; sputum one-half to one ounce daily. First inoculation, February 23d, ½ milligr.; reactive fever, 104.5° F.; forty-eight hours later, weight had fallen to 123 pounds; treatment discontinued five days; ½ milligr. repeated; maximum temperature, 99.2° F. From February 25th till March 4th, reactions avoided; patient gained to 125¾ pounds; sixth dose, 1½ milligr., reaction 102.4° F.; eighth dose, 2 milligr., reaction, 102° F.; reactions were successfully avoided during the subsequent treatments, ending April 24th; final dose, 8 milligr.; sputum ranged from ½ to 1 drachm during the last fifty-one days of treatment; April 24th, râles absent, dulness and bronchial breathing continue; weight, 130 pounds. Normal weight, 135 to 140 pounds. No medicine had been administered. Patient called home by illness of mother at end of April; reports on June 14th, "I now weigh 135 pounds, and am feeling stronger every day; seldom cough, sleep well, feel and look like myself, and am just making up my mind that the lymph has probably cured me." Gain, 12 pounds.

Case IV.—Mrs. J——, mulatto, aged twenty-eight, residence, Brunswick, Ga.; brother and all members of father's family died of tuberculosis; cough and failure of strength commenced July, 1890; since that time has lost 25 pounds in weight; right side, dulness, bronchial breathing, moderate moist râles down to sixth rib; dulness down to third rib, left side; evening temperature, 99.2° F.; daily quantity of sputum, 10 drachms; bacilli present; first treatment, March 13th, ½ milligr.; during March maximum temperature exceeded 99.2° F. but once, then reaching 100° F. On April 3d and 5th, following injections of 2½ milligr., temperature rose to 101.1° F.; treatment discontinued five days; patient suffered lassitude, loss of appetite, great depression; treatment resumed with no further indications of reaction until April 19th, when temperature rose to 101° F.; final dose, April 27th, 5½ milligr.; seventeen treatments administered; weight on entrance, 112¼ pounds; weight on April 28th, 122½ pounds; gain, 10¼ pounds; night cough somewhat lessened; quantity of sputum remains the same; physical conditions unchanged, excepting some diminution of râles. Reported June 24th, called home when she was doing very well; a letter from her a few days ago says she is failing rapidly.

Case V.—Mr. G——, aged thirty-one; residence in Florida for past six years; father died of tuberculosis; empyema, opened in May, 1890; six pints of pus removed; continuous discharge, at present two ounces daily, laden with bacilli; subject to frequent fevers; appetite poor; greatly emaciated; scarcely able to walk. First inoculation, February 8th; February 18th, patient reports good appetite for the first time in years; treat-

ment continues without reaction until the fourteenth treatment, 4 milligr. on March 29th, aroused a temperature of 103° F. Patient was greatly prostrated; dose reduced to 2 milligr.; no further reactive fever occurred. The dose on April 22d was 8 milligr.; 26 treatments; discharge reduced to one ounce. Normal weight, 165 pounds; weight on entrance, 126½ pounds; April 22d, 130 pounds. Reported July 7th, from Albany, N. Y., "weight, 130; discharge, 1½ ounce daily; continued gain in strength."

Case VI.—Mrs. D——, aged forty-two years; residence, Florida for past four months; one brother died of tuberculosis; disease followed influenza, January, 1890; has lost 19 pounds in weight during the past three months; dulness, bronchial breathing, moist râles over the whole upper lobe of right lung; slight bronchial breathing at right apex, evening fevers, night-sweats; beginning dose, March 18th, ¼ milligr.; final dose, April 23d, 6½ milligr.; no reactive fevers; expectoration diminished in quantity one-third; weight, March 18th, 115¾ pounds; April 23d, 118¾ pounds; reported June 24th—"Mrs. D—— gained after you left; she is now keeping house and feeling well."

In these incipient cases physical signs and microscopic examination established the diagnosis. The results may be attributed to tuberculin alone, since no other medicines than those mentioned were administered, and the patients were not subjected to climatic changes, excepting as noted. All patients had lived in fair circumstances, and previous to treatment good food had not been wanting; but until inoculations began both appetite and power of assimilation continued greatly impaired. In all but one, improvement has progressed in the two months subsequent to discontinuance of treatment, and this one, a mulatto, being of the mixed race which, it is well known, does not long survive the ravages of tuberculosis, offered gratifying improvement; the immediate decline on discontinuance of the treatment suggests that it had been a powerful support. In all cases râles diminished, other physical signs remained not appreciably changed. Evening temperatures exceeding 101° F. have contra-indicated immediate treatment. Gain in weight:

Case 1.	Gain in weight	from	January 27th	to April 23d,	17 pounds.
" 2.	"	"	Feb'y 17th	to April 23d, 20	"
" 3.	"	"	Feb'y 23d	to June 14th, 12	"
" 4.	"	"	March 13th	to April 28th, 10¼	"
" 5.	"	"	Feb'y 8th	to July 7th, 3½	"
" 6.	"	"	March 18th	to April 23d, 3	"

Advanced Cases.—Case I. D——, aged twenty-nine; residence in Florida, seventeen years; half-sister died of tuberculosis; since twelfth year occasional pleurisies; on entrance, sputum six to seven drachms daily; bacilli abundant; evening temperature during the week previous to inoculation, 99.7° to 101° F.; dulness over upper half of right chest; bronchial breathing; medium-sized infraclavicular cavity; dulness over fourth, fifth, and sixth ribs anteriorly, left side; no râles; past six months continued chest pains, frequent pleurisies on both sides; six liquid movements daily for four months; unable to work for past six months; first inoculation February 13th, one milligr.; no rise of temperature above 100° F. until 7 milligr., on February 25th, produced 101.2° F. No further reaction until March 19th, when 22 milligr. produced 101.5° F.; on the 20th, 101.6° F.; 23d, 101.6° F.; treatment continued without reactions up to a dose of 45 milligr. on April 22d. April 23d, râles disappeared; chest pains gone; sputum, two to four drachms daily; one to two daily solid normal movements. Cod-liver oil, taken previous to treatment, was continued. Morphia and bismuth administered for forty-eight hours. Weight, February 9th, 131¼ pounds; weight, February 16th, 128¼ pounds; weight, February 30th, 130½ pounds; weight, April 24th, 140¼ pounds. Gain, 12 pounds since treatment commenced. Reported June 24th, "repeated attacks of pleurisy after he left the hospital; lost flesh until he was down to his original weight."

Case II.—J——, aged thirty-seven; residence in Florida, four months; mother died of tuberculosis; patient has had chest affection for fifteen years; fever and night-sweats for many months; on entrance, left chest dulness, moist râles down to fifth rib; medium-sized cavity at third rib; sputum on entrance, six ounces daily; bacilli numerous; evening temperature, 99.5° F. to 100° F. First inoculation March 4th, 1 milligr.; temperature reached 101° F. on March 19th and 23d. On the 28th and 31st it reached 100° F. Temperature continued below 100° F. during April. On April 22d, 45 milligr. were administered, producing reactive temperature, 100.5° F. Maximum dose on the 29th, 60 milligr., when he is reported to have left the hospital. Normal weight, 170 pounds; entrance weight, 153 pounds; final weight, 157¼ pounds; twenty-one treatments; no medicine administered; reported at standstill, since treatment ceased.

Case III.—L——, aged forty-eight; residence, Florida; dulness over entire left chest; small moist râles over the upper lobe; large râles over the lower lobe; small cavities in the lower lobe; disease followed pneumonia; entrance temperature, 100.8° F.; first inoculation, ¼ milligr., March 14th, increased without reaction until 2 milligr. produced 102.8° F.; dose reduced to 1 milligr.; from April 2d to April 23d the maximum temperature never exceeded 99° F.; last dose, 5 milligr.; eighteen treatments; during first three weeks of treatment, diarrhœa excessive and persistent; during last three weeks diarrhœa checked and improvement was perceptible; sputum on entrance, two ounces daily; during the last week of treatment, ½ ounce daily; normal weight, 132 pounds; entrance, 119 pounds; end of third week of treatment, 112 pounds; end of sixth week, 115 pounds. Reported June 24th, and left hospital soon after your departure, unchanged.

Case IV.— K.——, aged thirty-nine; residence in Florida, two years; no hereditary tendency; cough and gradual wasting for three years; under observation in bed from March 9th until March 27th. From March 14th until March 19th maximum temperature ranged at or above 102° F.; right chest down to eighth rib, dulness, bronchial breathing, numerous moist râles; large infraclavicular cavity; left apex to second rib, marked dulness; bronchial breathing, small râles; sputum, 20 drachms daily; bacilli abundant; first inoculation, March 1st, ⅛ milligr.; on March 27th, ¼ milligr. produced reaction fever, 102° F.; maximum temperature continued between 102° F. and 103° F. until April 10th, when it fell below 100° F., so continuing under treatment until April 24th. As soon as temperature fell to 100° F., doses of tuberculin were again gradually increased, reaching 3½ milligr. on April 24th without reactions. Normal weight, 138 pounds; weight at the beginning of observation, 103¾ pounds; weight at the beginning of inoculations, 99¼ pounds. Reported June 24th: "Still under treatment; dose, 25 milligr.; weight, 103¾ pounds; maximum temperature, 99.5° F. to 100.5° F.; appetite improved; sleeps well; night-sweats occasionally; cough about the same."

Case V.—Miss L——, aged forty-five; residence in Florida for years; no hereditary tendency; hæmoptysis eight years ago; since which time she has gradually failed; cough and wasting of flesh increased since February 1st; dulness and râles over whole right chest above seventh rib; over fifth and sixth ribs anteriorly, indications of a medium-sized cavity; bronchial breathing at the left apex. April 3d, first inoculation, ¼ milligr.; April 23d, three milligr.; April 3d, weight, 112 pounds; April 23d, 115 pounds. Treatment continued two weeks longer. Reported June 24th: "Miss Lindsey calls herself cured. She says she is better than she has been for years."

Case VI.—H——, aged twenty-three; six months in Florida; father and brother died of tuberculosis; failing for the past twenty months; left chest presented moist

râles over the entire surface; entire dulness; large cavity between the second and third ribs anteriorly; right chest, apex dulness and moist râles down to the third rib; high evening temperatures, with profuse night-sweats; contra-indicated inoculation. Patient remained four weeks in bed until evening temperature fell to 101° F. During this time, weight had fallen to 111 pounds; treatment began on April 3d, with $\frac{1}{8}$ milligr.; maximum dose, $1\frac{1}{2}$ milligr.; normal weight, 145 pounds; entrance weight, 116 pounds; beginning of treatment, 111 pounds; April 23d, $113\frac{1}{2}$ pounds. Reported soon after your departure, left the hospital unchanged.

The advanced cases were rapidly failing before treatment began. Climatic influences remained unchanged; in all, appetite improved, decline in weight was checked, and disease was stayed. In the acute cases during treatment there was some slight improvement; in the chronic, decided. No unpleasant, complicating, or dangerous conditions were aroused.

In concluding our brief account of the treatment of tuberculosis by Koch's lymph, fever reactions having been prevented, it may be appropriately mentioned that too much has been demanded of this remedy. Eager hope of rapid cure, not held out by the discoverer, rendered the usually conservative medical mind ready to accept at first what approached the miraculous. The delicacy of lung tissue, with its readiness to inflammatory infiltration and the formation of connective tissue, makes the question of complete recovery with absence of physical signs, one for years to determine. All that can be logically demanded is improvement; a check in the downward progress, a commencement in the building-up. This result, tuberculin employed watchfully and with attention to details, has accomplished. Months may pass or years, yet no patient will find this treatment unsatisfactory, who sees his life bark drifting further away from the fatal eddy. Restoration to perfect physical strength, if achieved at all, must be sought along this same humble, often uneven, path of improvement.

Bar Harbor, July 12, 1891.

A CASE OF CHRONIC INTUSSUSCEPTION—DIAGNOSIS—AUTOPSY.

By CHARLES LEHLBACH, Jr., M.D.,

Newark, N. J.

The following unique and interesting case of intussusception came to my notice, and I report it on account of its pathological and clinical rarity.[1] It is to be regretted that no history was kept of the patient while in St. Michael's Hospital. The period covered is nearly four weeks, and a detailed history would have been of the greatest importance. As it is, I will have to rely upon the memory of the House Physician, Dr. Duffy, in presenting the patient's condition while in that institution.

I. K—, aged twenty-two, was admitted to St. Michael's Hospital on February 16, 1891. He had been sick ten days before admission. The symptoms manifest during this time and the nature of the onset of his illness cannot be ascertained. The seat of trouble seems to have been the abdomen. No history of injury or strain could be obtained. On admission to the hospital he complained of pains shooting across the transverse colon. He complained of a feeling of swelling in the abdomen which would come and go. No tumor could be felt. Bowels had not moved for some days. A full dose of castor-oil was administered. Subsequently the bowels moved freely, and according to the patient's statement he felt relieved. During his stay in the hospital his condition seems not to have been improved. It became necessary several times during the four weeks to administer castor-oil. A free evacuation seems always to have been the result. As no temperature was taken, I am unable to report whether fever existed at any time or not. Pulse is said to have been always normal when examined, and tongue clean. He was discharged as well on March 11, 1891.

On March 20th Dr. M. Seidman was called to the patient's home. During the doctor's short attendance the following conditions were noticed: The patient vomited at times, but the matters were never fecal. The temperature was about 102° F. mornings and evenings. There was no pain on pressing the abdomen. Bowels moved scantily on enemata of water. The previous history, especially the duration of the attack, somewhat clouded the case, but it was deemed expedient to remove the patient to the Newark German Hospital, in order to facilitate whatever treatment might be thought necessary.

Following is the history while at the German Hospital, where he died about three days after admission.

March 23d.—Temperature, $99\frac{3}{5}$° F.; was very restless and complained of pain in stomach; no pain in abdomen on pressure; slight tympanites.

March 24th.—Was seen on this day by several of the visiting staff, among them the writer. The patient had had a slight passage after an injection. He was very restless, with a small and wiry pulse. Slight pressure on the abdomen caused intense pain, especially on the left side. Tympanites very marked. Thighs semi-flexed. The patient's condition did not allow of any extended manipulation, although it was thought a deeply-seated resisting mass could be felt in the left lumbar and left inguinal region. Excepting the peritonitis, no definite conclusion could be arrived at.

March 25th.—Temperature, $98\frac{3}{5}$° F.; tympanites increasing. Other signs of acute peritonitis became more marked. The pulse was absent in the afternoon, and the patient died in collapse at 12.15 A.M., March 26, 1891.

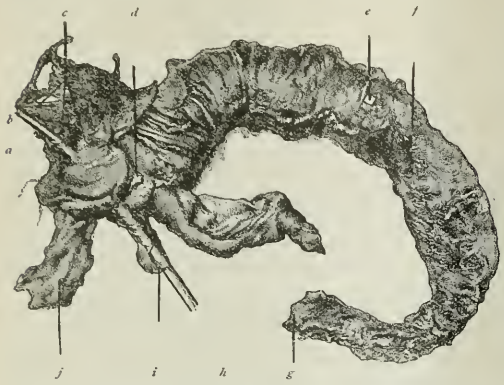
Autopsy.—The autopsy, made eighteen hours after death by the writer, revealed the following: Body: Emaciated. Lungs: Œdema and hypostatic congestion of both lungs; left lung slightly adherent at apex. Heart: Normal. Liver: Slightly congested; otherwise normal in appearance. Kidneys: Normal. Spleen: Normal. Stomach: Filled with yellowish-brown fluid which looked as if it might have been regurgitated from the small intestines; it was not fecal in character. Intestines: Distended with gas and at point matted together by a fresh exudate of fibrin and pus. Near the sigmoid flexure a small perforation of the colon was found, through which about one drachm of fecal fluid had escaped. This perforation was due to a slough of the intestine at that point.

One-half of the transverse colon and the greater portion of the descending colon presented the appearance of a hard, round, smooth tumor. It was found to be an intussusception commencing in about the middle of the transverse colon, and terminating at the sigmoid flexure two or three inches below the point of perforation of the outer layer. The mesentery of the duodenum was drawn into the invaginating intestine, binding down the duodenum firmly to the opening caused by the invagination. In the accompanying reproduction of a photograph taken by the writer, a catheter is passed through the duodenum. The portion of the duodenum which was bound down was a few inches from the pylorus. (The stomach was removed in the ordinary way. There is no intestine missing between that organ and the upper cut end of the duodenum, as seen in the cut.) At the beginning of the intussusception the bowel enclosed was in a semi-strangulated condition. The cæcum and vermiform appendix formed part of the invaginated bowel. The invaginating intestine measured about twenty inches, which would make about forty inches invaginated.

[1] Through the kindness of Dr. M. Seidman, who attended the patient for a short time in private practice, and of Drs. Duffy and Fleger, House Physicians of St. Michael's and the German Hospitals, respectively, I am able to present a fairly accurate history of the case.

It seems probable that the invagination commenced at the ilio cæcal valve.

In the above case, no matter how interesting the final, the real importance is to some extent lost by the incompleteness in the history of the first stage of the affection. However, it seems, even from the scanty history which could be gathered concerning the first five weeks of the case, that up to the time at which Dr. M. Seidman first saw the patient, we have had to deal with a purely mechanical condition of the intestine—an invagination coming on slowly, and not causing sufficient œdema, for at least a period of fifty days, to cause complete occlusion of the lumen of the intestine or to produce gangrene. If we can lay any stress upon the before-quoted statement of the patient, when he complained of a swelling which comes and goes, it seems that the intussusception was not a progressive one, but that there were periods when the invaginated bowel was partially withdrawn from its invaginating sheath.



a, Cut end of duodenum, a few inches from pylorus; *b*, Catheter; *c*, Mesentery spread out showing its entrance into invaginating intestine; *d*, Beginning of intussusception; *e*, Perforation; *f*, End of intussusception; *g*, Rectum, a few inches from anus; *h*, Ilium; *i*, Duodenum (catheter passed through it); *j*, Pancreas.

Progress of Medical Science.

Chronic Interstitial Myocarditis.—According to Drs. Bard and Philippe, in interstitial myocarditis moderate hypertrophy of the heart is a constant phenomenon, with dilatation of its cavities, particularly of the left ventricle. On section, the color varies according to the degeneration of the muscle. The thickness of the ventricular wall is not uniform; it is more especially thin at the apex. The interstitial change is visible to the naked eye in lines or plaques. The papillary muscles are particularly affected. Whenever cardiac hypertrophy is present with no valvular disease, myocarditis should be thought of. Microscopically, the patches of sclerosis are made up of bands of fibrous tissue, and the muscular elements are atrophied. If the process is rapid, cellular elements predominate. In the plaques, the vessels show a periarteritis; elsewhere there is no constant change found in them. The authors do not believe the disease to be of vascular origin, for the inner coat of the vessel is healthy. In the other viscera the effects of chronic congestion are seen. Many confound this interstitial myocarditis with the sclerosis set up by vascular disease. In the senile heart like changes arise, due to progressive obliteration of the small arteries. As to atheroma affecting the large branches of the arteries of the heart, most often one of the chief trunks near its origin is involved, from which a true angina pectoris may result. Rarely a branch may be completely obliterated, giving rise to necrotic foci. This interstitial myocarditis is not due to hypertrophy the result of valvular disease, for the latter is seldom present. Nor is it the outcome of renal disease, for in purely primary forms of nephritis this diffuse interstitial myocarditis is never seen. Nor is it due to diseases of the lungs, for then the right side of the heart would be chiefly affected. It is really a primary myocarditis. The changes in the muscular fibres are degenerative, without any signs of inflammation, whereas those in the interstitial tissue are active. Thus the changes in the latter are primary. In the course of infective diseases inflammatory lesions are apt to take place in the interstitial tissue, and these may become chronic. Two sets of agents may set up this inflammatory sclerosis of the myocardium: 1, intoxications from alcohol, lead, gout, etc., and, 2, infective diseases—enteric fever, diphtheria, pyæmia, eruptive fevers, syphilis, though here the pure interstitial myocarditis must be distinguished from the sclerosis due to syphilitic endarteritis and tubercle. Rheumatism, which may in any of its forms set up myocarditis, occupies as it were an intermediate position between these two classes of diseases.—*Revue de Médecine.*

The Bacteriology of Glanders.—From a careful study of this subject Dr. Finger, of Vienna, has arrived at the following conclusions: 1. Successive local injections of the bacilli of glanders into animals susceptible to the poison produce with each injection symptoms of gradually diminishing virulence—that is to say, the first injection only produces the typical nodules, the later ones causing an abortive type of the disease. 2. The constitutional symptoms of glanders after intravenous injection of virulent cultures produces an incomplete local immunity, and an abortive course after subsequent local injections. 3. Intravenous injection of virulent cultures quickly causes death in some animals—sometimes in a few hours; in such cases post mortem examination fails to discover any local manifestation of the disease. 4. Intravenous injection of a sterilized culture of the bacilli of glanders produces in rabbits an immunity against the infection from pure cultures which lasts from three to six weeks. Local manifestations, however, occasionaly appear, these being of an incomplete nature and not followed by any constitutional symptoms. At the end of the above-named period, however, the injections are followed by a typical and rapidly fatal disease. 5. Rabbits which have survived an ordinary attack of the disease enjoy afterward complete immunity. Repeated local injections simply produce a transitory local affection, constitutional symptoms never following. 6. This immunity does not appear to be able to be tranferred to the offspring—that is to say, does not become hereditary. 7. The injection of sterilized cultures of the bacilli or of their chemical products produces poisonous effects, generally mild in character, but sometimes so severe as to kill the animal. Post-mortem examination reveals the same lesions as are seen in the primary disease, localized mainly in the portal system. 8. Injections of sterilized cultures produce an immunity, though not always complete, against intravenous injection of virulent cultures. 9. If sterilized and virulent cultures are injected at the same time, the disease produced is exceedingly rapid and fatal. 10. The bacilli when introduced into the tissues of susceptible animals exhibit great activity, multiplying rapidly, growing into long threads, and apparently defying the action of the phagocytes. 11. In the tissue of non-susceptible animals, such as white mice, the bacilli show no signs of activity; they rapidly die and disappear. There seems, however, to be no intervention of leucocytes. 12. In rabbits which have been rendered artificially proof against the poison the bacilli seem to take longer in disappearing. There is rapid collection of leucocytes, with some exudation. 13. The rapid death of the bacilli in the white mice is probably to be referred to an active power of destruction possessed by the organism. 14. The slower disappearance in other animals is to be re-

ferred to the action of the leucocytes, which appear to play a special *rôle*, as described by Metschnikoff under the term of phagocytosis. But, in addition to this, Dr. Finger considers that the fluid of the tissues themselves play a prominent part in the destruction of the microbes.—*Wiener Medicinische Wochenschrift.*

Jaundice in Childbed.—Dr. Labusquière relates the following case. He attended, in December, the confinement of a married woman of emotional temperament. The catamenia were always painful, and associated at their commencement with sharp hypogastric pains and marked anæmia. Attacks of urticaria were frequent. She burst into tears on one occasion because the doctor called and saw her before she had time to adorn herself like a fashionable convalescent. Labor was lingering, and the forceps was applied under chloroform. She manifested extreme alarm when informed that the use of instruments and chloroform was necessary. The child was saved. On the second day the patient was observed to be jaundiced. There was no pain in the hepatic region, but the gall-bladder was very tender on pressure. The milk, as well as the urine, contained biliary pigments. The jaundice subsided within a few days; as it disappeared the patient was troubled with severe itching of the skin and a mild attack of urticaria. The patient made a good recovery, and was able, after the cessation of jaundice, to suckle her child. Dr. Labusquière refers to the icterus of menstruation noted by Senator and others. Pilliet has recently written on the liver in eclamptic cases, and jaundice occurring in puerperal eclampsia is an extremely grave symptom. In Labusquière's case the jaundice was simple. The lingering labor might have involved much disturbance of the circulation in the liver. The chloroform might have played some part in causing the complication, though not quite two ounces were used for a long forceps delivery. It appears most probable, however, in the author's opinion, that mental agitation was the cause of the jaundice. Emotion may set up vaso-motor disturbance in the liver and consequent excessive secretion of bile. On the other hand, it may act, as Potain believes, by causing spasm of the muscular elements of the bile-ducts. The patient had been a spoilt child, and her health was permanently enfeebled by severe attacks of several febrile disorders in infancy.—*Revue Obstétricale.*

The Hypodermic Injection of Camphor.—The employment of camphor hypodermically in solution in oil, alcohol, or alcohol and ether, is much more general on the Continent than in England. German and Russian practitioners esteem it a valuable method of treating symptoms of impending collapse. Dr. Alexander, of Berlin, has published a paper giving the results of an extensive series of observations made during the last two years on the effects of hypodermic injections of oleum camphoratum (composed of one part of camphor to nine parts of olive-oil) in a large number of cases of disease of the lungs. The dose given was fifteen minims once a day. As the effects of camphor are cumulative, it was found that four daily injections were as much as could usually be borne without some unpleasant effects, such as headache and restlessness at night. After an interval of a week, however, one more injection could be given without causing any unpleasant symptoms. Phthisical patients seemed to bear continued treatment better than others, and its results in the last stage of phthisis were very valuable, the night-sweats, the irritating cough, and the expectoration being diminished in a remarkable manner, even the first dose effecting a very noticeable improvement in the patient's condition. In hæmoptysis the method also proved very useful, patients being enabled to get about again without fear of a recurrence more rapidly than under ordinary methods. Camphor injections administered in bronchitis increased the secretion at first, and afterwards caused it almost to disappear. They did not seem to be of much use when there was also emphysema. In pneumonia their value was especially marked in weakly individuals or in those with cardiac disease, and they cut short follicular tonsillitis and acute coryza. It was found that in some cardiac cases, where digitalis had ceased to be of benefit, after a few camphor injections, it could be again given with good results. These injections must, of course, be given to children only in very small quantities, but no effect appeared to be produced on the infants of mothers who were being treated by camphor injections for catarrhal pneumonia. —*Berliner klinische Wochenschrift.*

Atrophy of the Mucous Glands of the Stomach.—Our knowledge of the pathology of diseases of the digestive tract has received many important additions during the last few years, but it is still by no means complete, and compares unfavorably with what we know of the cardio-respiratory apparatus. This is due to some extent to the comparatively few diseases of the stomach and intestines which are met with in this country. In the East, however, intestinal troubles are as frequent and multiform as chest complaints are in our country. Under the term "tropical diarrhœa" are included probably many different diseases of the intestinal tract. One of these, known as "sprue," has recently been shown to be due to an atrophy of the mucous glands of the small intestine. According to Professor Nothnagel, atrophy of the glands of the stomach is not such a rare disease, even in Europe, as is generally supposed. He records the case of a man aged forty-eight, who for some time had been complaining of increasing anæmia, loss of weight and appetite. The temperature was also somewhat raised when the patient first came under notice, but was brought down to normal by the use of quinine. On examination, the abdomen was sunken, and in the inguinal region the glands were rather large, but nothing further abnormal could be detected in any of the organs. There was occasional vomiting. Examination of the vomited matters demonstrated that there was a deficiency of hydrochloric acid in the contents of the stomach; no sarcinæ were found. Professor Nothnagel made a diagnosis of atrophy of the mucous membrane and glands of the stomach, and founded it on the following grounds: The patient had suffered for some years from loss of appetite, this being the chief symptom of which he complained, and, as just stated, the gastric contents were found to be deficient in free hydrochloric acid. It is true that this is also the case in carcinoma of the stomach, the condition which the disease now under consideration is most liable to be mistaken for. This deficiency, however, is by no means pathognomonic, though it would naturally be most marked when the glands of the stomach were much affected. In this case no tumor could be detected in the region of the stomach; there had been no pain, and until shortly before the patient came under notice there had been no vomiting. Taking the time the disease had lasted into consideration, with these symptoms, cancer of the stomach had to be excluded. Malaria was also improbable, as there was no swelling of the spleen. Professor Nothnagel remarks that there are several forms of the complaint. In one the glands as well as the mucous membrane completely disappear, and this may often occur together with a scirrhosis of the organ. In another form the whole thickness of the stomach is atrophied, and its walls become transparent and as thin as paper. In such conditions the submucosa as well as the mucosa will be found to have disappeared. In a third form, which is the most common, the atrophy of the glands follows upon a gastric catarrh. The chronic inflammation leads to an increase of connective tissue; this gradually contracts around the glands, and so destroys them. In this way retention cysts are sometimes formed, as in the kidney. As regards the grognosis, this is naturally grave, as little can be done to prevent the spread of the disease. The treatment consists in the administration of hydrochloric acid and pepsine.—*The Lancet.*

Laparotomy for Wounds of the Liver.—At a recent meeting of the Paris Société de Chirurgie, Dr. Terrier spoke on laparotomy for wounds of the liver and cited two cases. One was that of a hard drinker who received in a quarrel a stab of a knife in the abdomen. Laparotomy was performed and a cirrhotic liver was exposed. An attempt was made to suture the wound, but the ligatures tore through the substance. The hepatic wound was subsequently plugged, and the abdominal incision closed. The patient died from peritonitis, but all bleeding had been effectually arrested. The other case was that of a man who had a wound of three inches in length in the liver. This wound was sutured, but another which had escaped notice caused death by hemorrhage. Dr. Terrier maintains that wounds of the liver are not inaccessible to surgical intervention, and that life can be saved by properly examining the organ, so that no wound escapes observation.

Indications for Trephining.—Dr. J. B. Deaver gives the following indications for trephining: 1. Simple depressed fracture with or without brain symptoms. 2. Compound depressed fracture with or without brain symptoms. 3. Impact fracture, simple or compound, with or without brain symptoms. 4. Comminuted fracture, simple or compound, with or without brain symptoms. 5. Compound fissured fracture with depression of bone without brain symptoms. 6. Compound fissured fracture with depression of bone with brain symptoms. 7. Compound fissured fractures with depression of bone and without brain symptoms in which there is bleeding through the fissure or fissures. 8. All punctured, incised, and gunshot fractures.—*Annals of Surgery.*

Urethane in the Urine.—Dr. Rademaker gives the results of his examination of large quantities of albuminous urine. He has always found present in such urines a crystalline organic compound soluble in water, ether, chloroform, alcohol, and benzol, and almost insoluble in petroleum ether. This compound is isolated by evaporating several pints of albuminous urine to dryness on a water bath, and extracting the residue with ninety eight per cent. alcohol, and filtering. The alcoholic solution is then allowed to evaporate at a low temperature. The oily residue is treated with dilute sulphuric acid, and extracted with ether, and the ether allowed to evaporate spontaneously. The residue was found to contain urethane in an impure state. By further treatment the impurities were got rid of and the substance deposited in crystals. Normal urine, on being treated in the same way, did not yield a trace of urethane; but if an alcoholic extract of such a urine was evaporated at a high temperature, urethane was always formed. Dr. Rademaker is of opinion that in the presence of this substance, which is a powerful narcotic, is to be found the explanation of uræmic coma.—*American Practitioner.*

The Mechanism of Immunity from Infection.—Drs. Emmerich and Mastbaum have published an article on the cause of immunity from infectious diseases and their treatment, especially of swine erysipelas, and a new method of protective vaccination for it. Emmerich published in the year 1886 his doctrine that the cause of immunity from infectious diseases is a modification of the chemical process going on in the cells, so that the new chemical compounds formed act as microbe-killers without doing any harm to the cells themselves (*The Lancet*). In consequence of the results of a series of experiments, Emmerich concluded that the antibacterial poison acts destructively on all the microbes within a few hours after their introduction into the organism. The publication of this doctrine having met with a good deal of opposition, he repeated his experiments, and again arrived at the same result, showing that the explanation of immunity from infectious diseases proposed in 1886 was justified. Granted the correctness of this, it follows that extracts from the tissues of any animal enjoying immunity are remedies against the corresponding infectious disease. Further experiments are now reported by Drs. Emmerich and Mastbaum, which show that an extract from the various tissues and the blood of rabbits, which have been made proof against swine erysipelas, is an excellent remedy for the disease, and that a hypodermic injection of the extract can serve as a rational protective inoculation. A rabbit was inoculated by having injected into the posterior auricular vein the fifth of a cubic centimetre of a fresh broth culture of swine erysipelas, diluted with fifty times its volume of distilled water. In the course of the following week or two a series of hypodermic injections of the same liquid was administered. For the purpose of preparing a liquid extract suitable for therapeutic or prophylactic purposes, the organs of the rabbit were cut up and submitted to a pressure of from three hundred to four hundred atmospheres, and the expressed juice filtered into sterilized bottles. A large number of white mice as well as rabbits were now inoculated with the swine erysipelas, and at the same time, or very shortly afterward, an injection of the liquid extract was administered to some of them. These remained alive, while all the others—that is to say, those which had not received an injection of the liquid extract of the organs of the infected rabbit—succumbed. Other experiments were carried out by which it was shown that this same liquid extract is capable of conferring immunity from the disease. Further experiments were made which showed that most of the bacilli were destroyed in six hours, and that in eight hours all were dead, or at least incapable of multiplication, but that the liquid extract produced extremely little effect upon the same bacilli outside the organism, so that the presence of living cells is evidently necessary for the destructive effect of the liquid extract to manifest itself. Another interesting result obtained was that bacilli taken fresh from the body were very much more active than their cultures in broth.

Employment of Exalgine in Infants.—Dr. Moncorvo has published the following *résumé* of his observations: 1. The marked activity of exalgine as an analgesic has been well demonstrated in twenty-one different children varying from one to twelve years of age, in whom it was administered in various painful affections. 2. In all the children the medicine was well borne. 3. None of the complications, such as ringing of the ears, nausea, and dizziness, sometimes stated to have been observed in adults as a consequence of exalgine, were noted. 4. Exalgine was employed at first in the dose of three-quarters of a grain daily, gradually increasing up to five grains. 5. Since exalgine is not disagreeable to the taste, it was given to most of his patients in substances applied directly on the tongue, while in some it was suspended in diluted wine. 6. Exalgine exceeds antipyrin in activity, and the same effects may be expected from it as might be looked for from a dose of antipyrin five times as large.—*Bulletin Général de Thérapeutique.*

Stricture of the Duodenum.—According to Dr. Boas these strictures fall into two classes, for they either lie above or below the orifice of the ductus choledochus. The former resemble clinically, and cannot be diagnosed from, stenosis of the pylorus, whereas the latter can almost always be definitely localized. The signs most to be relied upon for the purpose are the constant presence of bile or bile-stained chyme in the stomach, the concomitant presence of pancreatic juice mixed with the bile in the stomach, the presence of a considerable amount of indican and of acetone in the urine, and, lastly, the clayey condition of the stools. Special attention is drawn to the importance of testing the contents of the stomach in these cases for pancreatic juice. Where such is absent the pancreatic secretion is probably arrested, or the duct blocked, and the stricture is not unlikely caused by some affection of the pancreas.—*Deutsche medicinische Wochenschrift.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, October 17, 1891.

THE PATHOLOGY AND TREATMENT OF PUERPERAL ECLAMPSIA.

IT is not long since the subject of puerperal eclampsia was ably discussed before the New York Academy of Medicine, and the views at that time expressed were laid before our readers. But it cannot be said that positive conclusions have yet been reached regarding this important topic, and we believe that the discussion on puerperal eclampsia which took place before the British Medical Association last July will interest our readers.

Dr. A. L. Galabin, of London, opened the debate. He showed that there was a pretty general uniformity of belief that the convulsions are due to some kind of renal impairment. But he showed that this does not quite solve the problem, since it is necessary to know what causes this renal disease. The experiments of Dr. Blanc were cited as indicating that in the urine of eclamptic patients there is a specific bacillus which, when cultivated, causes convulsions in some lower animals. Dr. Blanc thinks that this bacillus causes not only the nephritis, but also the convulsions directly. Bearing on this point Dr. Byers cited the investigations of C. Leyden. This observer examined the kidneys of three fatal cases in which there was eclampsia associated with albuminuria, and found "the kidneys large and pale, the cortex yellowish and dull. Microscopic examination showed a very extensive loading with fat, especially in the tubuli contorti; to some extent also in the glomeruli, and in the Malpighian capsules. The fat was distinctly present in large drops." When the kidneys had remained for a time in spirits the fat in great part disappeared, and then the organs, on microscopic examination, appeared to be normal, and accordingly he infers that this fatty condition is not a degeneration, but an infiltration. His view is that such morbid conditions are due to a prolonged arterial anæmia. He thinks it also explains the rapid recovery that so frequently follows delivery. Further, he regards as causes the changed conditions of pressure which affect the abdomen or the effluent urinary organs.

Dr. Auvard's view, that eclampsia is the result of a "strike" on the part of the organs of elimination, especially the kidneys, no doubt represents a truth, but hardly goes deep enough to be called a scientific explanation.

The same may be said of the theory of Stumpf, that under certain circumstances a nitrogenous substance of a toxæmic nature—it may be acetone or a closely allied body—is developed, which in its elimination irritates the kidneys and so causes a nephritis.

It seems that we do not know, as yet, more about the pathology of eclampsia than that there is some convulsive poison thrown into the blood, either through renal disease or infection, or both.

The subject of the therapeutics of eclampsia is more interesting, though here also no great unanimity of opinion was reached. According to Dr. Auvard the mortality from no treatment at all is only twenty-five per cent., while that following active interference is thirty-one per cent. Nihilist therapeutics should make a note of these figures. Dr. Galabin, however, gives the percentage of mortality at Guy's Hospital, under venesection, as thirty per cent., while under the use of chloroform it was 20.5 per cent. These figures, however, do not do justice to venesection, since they apply to the period when antisepsis was not used. Dr. Galabin himself favors venesection in certain cases, especially venesection in large amount (forty ounces). Auvard's mortality with venesection was thirty-five per cent. Dr. J. G. Swayne, in an experience with thirty-six cases, found venesection the most efficacious remedy, chloroform and chloral next, and delivery third. Most of the other speakers recommended chloral and chloroform, and venesection in plethoric cases. Little reference was made to the use of morphine, or hot baths, or pilocarpine, and on the whole we should say that English physicians depended chiefly on the chloral-chloroform treatment. The morphine treatment, which may be considered especially an American one, is evidently but little used.

THE VIRCHOW TESTIMONIAL.

THE celebration of the seventieth birthday of Virchow, at Berlin, on Tuesday last, was one of the events in medical history which points a moral for honest scientific work and accentuates the crowning glory of a long and distinguished career. It falls to the lot of few indeed to be the recipient of honors thus worthily bestowed, and to realize the appreciation of such a widespread constituency of learning, talent, and power. The tributes to his worth were those which even his Emperor might have envied, coming as they did from every portion of that higher world of science, thought, and learning in which he himself was a recognized leader and king. It is a pleasant task for his medical brethren to congratulate him on the event, and share with him, even indirectly and collectively, the honor of a common brotherhood in science. A salon in the Kaiserhof was handsomely decorated for the occasion, and seated in it Virchow received the good wishes of thousands of his friends. There were present nearly all the prominent men of science in the city, while letters of congratulation, telegrams, and cablegrams focussed kind remembrances from distant portions of the globe.

At noon a birthday book, compiled by a number of Virchow's former pupils, was placed on sale, and at the same time one of the finest streets in the city was rechristened Virchow Strasse. The Professor's birthday was also made the occasion for a demonstration, in a mild and amiable sense, upon the part of the Freisinnige party (Progressists), now known as the Independents, of which section of the German Liberals Virchow has always been a recognized parliamentary leader.

During the course of the day Herr Richter, at the head of a deputation of the Freisinnige party, presented the Professor with a number of presents. At about the same time Mayor Forckenbeck presented Virchow with the deeds conferring upon him the freedom of the city of Berlin. A gold memorial medallion was also presented to the Professor by a committee of his medical and political colleagues, and bronze copies of it were given to every member of his family, and were sent to every scientific institution in Germany with which Virchow has at any time been connected.

But the best of all is that Virchow is hearty and well, and is still working with as much spirit and interest as when, twenty years ago, he first won his membership to the Academy of Sciences. Let us hope that his life may be prolonged many a year, and the rounding of his career may be yet fuller of those good works by which he has already made himself so famous. The medical profession of America sends its greeting accordingly.

THE NEED OF ASEPTIC RIVERS.

The rivers of New Jersey and New York are becoming a source of suspicion and alarm instead of being an inspiration to pleasant fancies and successful agriculture. The Passaic, about which poets might have sung, if poets had any chance in New Jersey, is, we are told by that stern censor of our fluvial treasures, *The Sanitarian*, "well known to have served the double purpose of being the common receptacle of the sewage, and the source of the potable water, of one hundred thousand people, more or less, for many years."

The glorious Hudson also is said to supply to the inhabitants of Albany, attenuated solutions of the sewage of Troy, until Albany has become celebrated as "a fever-hatchery." As for the Croton, no one dares speak a kind word for it, for every person in New York with a diarrhœa thinks sadly of that poisoned stream. Verily the rivers of to-day may be beautiful or not, but they must be clean or they will not be tolerated. The bacteriologist with his culture-tubes must endorse a river as aseptic before its beauties can be sung or its waters drank. It is temporarily comforting, however, in this connection to know that by the latest analysis the Croton is found to be free from nitrites. Long may it thus flow.

THE EMPEROR'S EAR.

A *Sun* correspondent, writing from Berlin under date of October 4th, says the chronic affection of the Emperor's ear has developed a strong tendency to disturbance of temper. This may in a measure be true, but of far greater importance is the danger to life itself in these cases. Indeed, examples of a fatal termination are to be expected in a considerable number of instances, occurring from childhood to beyond the active period of life; and it is, therefore, a matter of the utmost surprise that, in a personage whose life is of such importance to Germany, a disease of this kind is allowed to progress unchecked. The frequent exacerbations to which, it would seem, his majesty is subjected from exposure, and colds arising therefrom, may at any time be followed by an extension of the aural inflammation to the brain. The MEDICAL RECORD has on former occasions called attention to this possible complication, both on account of the patient's important social and political position, and the possible effect of neglecting a disease of such a treacherous character. It seems like living again in the dark ages to read of the danger to which the young Emperor of Germany is exposed for want of that surgical treatment to which chronic suppurative otitis is now known to be amenable. Sexton, an American authority on the ear, who cites in his book the cure of many similar cases, calls attention to the fact that the operative treatment for the relief of purulent affections of the ear originated in the very country of which the distinguished patient is emperor.

THE SHIP SURGEON.

Life on the ocean wave is less poetical and attractive to the medical man whose life-work is on shipboard than even he himself thought it would be when he entered it from necessity, and even the one who joins a ship's company from choice finds it disappointing in many respects. It is not altogether an easy life, and now to add to his hardships the Massachusetts Supreme Court has handed down an opinion making the surgeon, and not the company which employs him, the responsible party, and the one against whom action is to be brought by a passenger believing himself to have been maltreated *en route*. If the patient deems himself to have been treated for his ills, injuries, or infirmities in an unskilful or careless manner he must now sue the surgeon for damages, and not the company by whose vessel he was being carried. The opinion reads:

"The law does not put the business of treating sick passengers into the charge of common carriers. The work which the physician or surgeon does in such cases is under the control of the passengers themselves. It is their business, not the business of the carrier. They may employ the ship's surgeon or some other physician or surgeon who happens to be on board, or they may treat themselves if they are sick, or may go without treatment if they prefer; and if they employ the surgeon they may determine how far they will submit themselves to his directions and what of his medicines they will take and what reject, and whether they will submit to a surgical operation or take the risk of going without it."

In one respect this ruling of the Massachusetts Court raises the standard of the ship's surgeon, taking him from the rank of common employee of a company and making him the equal of his land-lubber brother—a sovereign capable of suing and of being sued.

THE BIOLOGICAL TEST OF URINE.

Professor Semmola, of Naples, has proposed an addition to our present clinical methods which has at least the merit of novelty. He advises that in various acute diseases the urine be tested not only chemically but "biologically," *i.e.*, that specimens of it be injected into dogs, guinea-pigs, or rabbits, in order to determine the degree and kind of its toxicity. This biological test can, he thinks, be used by the clinician, and will throw light upon the course of the patient's disease. Bouchard has shown that the urine possesses different degrees and modes of toxicity in different diseases, this being due to the presence of leucomaïnes, ptomaïnes, and various other

products of tissue and microbic activity. M. Semmola seems to think, so far as his written contribution shows (*British Medical Journal*, September 19), that the animal experimented upon in any given case will reproduce some of the symptoms of the patient's disease. We cannot better illustrate this fact than by reproducing the account of one of two cases which he describes. This was a case of fibrinous pneumonia following influenza; and Professor Semmola states that while the specific inflammatory process successively invaded new zones of pulmonary tissue, there supervened suddenly eclamptic and tetanoid symptoms which made the medical attendant suspect the onset of infective cerebro spinal meningitis. The condition of the patient was most serious: a temperature of 40.07° C.; pulse 125, respirations 55; fluid yellowish-green expectoration, profuse sweating, etc.; in short the classic picture of a most violent acute infection. The doubt as to the diagnosis was fully warranted, and it will readily be understood of what importance that was relatively to prognosis and treatment. Semmola did not, however, feel justified in accepting without much reserve the diagnosis of cerebro-spinal meningitis, and before giving his opinion he caused experiments to be made in the laboratory of the Clinical Institute on the biological analysis of the urine which the patient had passed in the last twelve hours. The experiments were conducted by Dr. Traversa and Dr. Falcone.

The result of that biological analysis was as follows: Urine deep yellow in color, clear, acid, specific gravity 1.020, containing no chemically appreciable pathological elements, no uroerythrin, biliary pigments, or ethyldiacetic acid. The injection of 5 c.c. of this into a guinea-pig weighing 250 grammes, and of 10 c.c. into a rabbit weighing 1,050 grammes, was immediately followed by general tremors, alternating with tonic convulsions and extreme dyspnœa, exactly resembling the clinical symptoms and convulsions seen in the patient, and clearly showing that part of the dyspnœa, the severity of which was certainly disproportionate to the extent of the pneumonic process, was of bulbo-paralytic origin. The professor no longer hesitated as to the diagnosis, but declared that the convulsions did not indicate an attack of cerebro-spinal meningitis, but simply a most acute intoxication, due to the formation of new special ptomaïnes, in that great and mysterious bio-chemical laboratory of which the human organism, when attacked by influenza, is the seat.

Iodide of sodium was thereupon given, and the patient recovered.

The story of the other patient was one of much the same kind.

M. Semmola is a professor in the University of Naples and a senator of the Kingdom of Italy, and his biological experiments are interesting. But the train of reasoning which he offers to us seems very transcendental, and one is tempted to exclaim, after a careful perusal of the senator's paper: "In the name of the Prophet, Bosh!" We do not wish to do our esteemed colleague injustice, however, and it may be considered that the above exclamation is not officially made. We will wait until he has published his experiments in full, and add in justice to him the following paragraph, with which he concludes his article:

There are, he says, two indispensable conditions for attaining all the clinical advantages which may be looked for from biological analysis: 1. The researches should be carried out by assistants thoroughly versed in pharmacological experiments, especially those concerning the nervous and muscular systems. 2. The experiments should be begun with small doses of urine (always having regard to the body-weight of the animal), because in acute infective diseases the organism sometimes gives rise to the formation of most powerful poisons, with regard to which it would be impossible to obtain a precise knowledge of the clinical symptoms of intoxication produced by them, unless one proceeded step by step. Lastly, the reader need hardly be reminded that the total quantity of urine passed in the twenty-four hours should be taken into account wherever it is possible to do so.

News of the Week.

American Orthopedic Association. — The following officers were elected for the ensuing year: *President*, Benjamin Lee, of Philadelphia; *Vice-Presidents*, R. H. Sayre and H. L. Taylor, of New York; *Corresponding Secretary*, Royal Whitman, of New York; *Secretary* and *Treasurer*, John Ridlon, 337 West Fifty-seventh Street, New York.

American Public Health Association.—The nineteenth annual meeting will be held at Kansas City, October 20 to 24, 1891. The Local Committee of Arrangements announces that all the Railway Passenger Associations of the county, have granted a one and one-third fare rate for the round trip on the usual certificate plan. The delegate must procure a certificate of attendance from the agent at the starting point by paying full fare to Kansas City, and then have the certificate of attendance signed by the proper officer of the Association at Kansas City. This certificate will then procure return ticket for one third fare. All the leading hotels of Kansas City will give special rates to delegates. Arrangements are being perfected for an excursion into Kansas as one of the features of the meeting. Further information as to the meeting may be obtained by addressing Dr. E. R. Lewis, Chairman, or Dr. Joseph Sharp, Secretary, Local Committee of Arrangements, Kansas City, Mo.

An Office Swindler.—Medical men of New York are hereby notified to beware of a powerfully built man with well sunburned face, mustached, who calls himself an engineer, displays considerable knowledge of steam engines and of maritime and custom-house matters; claims to bring a box of curios from South America or other countries from a physician's old patient whose name he obtains, as well as that of the physician upon whom he calls, by a process known to himself and confederates only.

Dr. Frank W. Reilly, of Chicago, has been appointed Secretary of the State Board of Health of Illinois in place of Dr. Rauch, resigned. Dr. Reilly was once a doctor, but of late has been a journalist, and brings to his position the advantages of "a trained pen," a well-balanced head, and broad grasp of things in general. As managing editor of the *Chicago Daily News* he has

proved what a doctor can do in successfully running a great newspaper. We wish him success in his new office.

A Notable Union.—The doctors of Northern Ohio will gather at Mansfield, November 5th to 7th, for at that time and place the three societies of Northern Ohio, viz., the Northwestern Ohio Medical Society, the North Central Ohio Medical Society, and the Northeastern Ohio Medical Society, hold a union meeting.

Illinois Army and Navy Medical Association.—The Illinois Army and Navy Medical Association was organized at Springfield, Ill., June 26, 1890, with Dr. Hosmer A. Johnson, of Chicago, as President, and Dr. John H. Rauch as Secretary. The objects of the Society are the promotion of social intercourse and historical and medical subjects connected with the late war. All reputable physicians now living in Illinois, whether in practice or not, who served in the Army or Navy during the late war, and all who were Surgeons, or Acting Assistant Surgeons, who were with Illinois troops, and are now non-residents of the State, are eligible to membership. At the second meeting of the Association, held in Springfield, May 18 and 19, 1891, Dr. John H. Rauch was elected President, vice Dr. Johnson, deceased, and Dr. Edward P. Bartlett, of Springfield, was elected Secretary. The Association met again in Chicago, October 7th and 8th.

Curiosities in Science.—John Hunter was five feet two inches high, so says Mr. William Clift. Double monsters, says Dr. Baudain, are more frequent in Central Europe than anywhere else, as also are twins. The Barnums, when in search of "phenomena," invariably go to Hungary, Austria, and Galicia.

Prodigiously Prolific.—A single germ, says Cohn, under good conditions could multiply in three days to 4,772 billions, and make a mass weighing 7,500 tons.

The Utility of Filth.—Sweet are the uses of adversity, but richer and more fructifying is, in some contingencies, the utility of filth. At least such seems to have been the case with Anthony van Leeuwanhoek, who gave the first accurate description of bacteria, and who got his material from the teeth of an old man who never cleaned his teeth. After all, why should not the old man, with his rich dental microbic cultures, share a little of the immortality of Leeuwanhoek?

The First Colored Female Doctor.—We are informed by Dr. A. S. Houghton, of Seymour, Conn., that the despatches were incorrect in saying that the first colored female doctor had just passed the Alabama State Board. Dr. Consuela Clark, a colored lady of Cincinnati, O., has practised medicine since 1886.

The Bacteriological vs. the Chemical View of River Pollution.—Yet there are said to be some people, and among them even some physicians, who still hold to the fatal fallacy of the late Dr. Letheby, Medical Officer of Health of London, about twenty-five years ago, that "sewage, when it is mixed with twenty times its volume of running water, and has flowed a distance of ten or twelve miles, is absolutely destroyed; the agents of destruction being infusorial animals, aquatic plants and fish, and chemical oxidation." This theory appears to have been based upon Dr. Letheby's inability to detect the sewage under such circumstances, hence he believed in its total destruction, notwithstanding abundant evidence adduced of the prevalence of cholera and typhoid fever among persons who drank such water. He had more faith in his chemical tests and microscopes than in the fatal results. Unfortunately, Dr. Letheby's theory appears to have been accepted by Professor Chandler, of New York. It was on his judgment that the people of Albany consented to drink the sewage of Troy; and it has been through faith in his analyses and judgment that the Croton and Hudson have been held up as examples of purity, notwithstanding the amount of filth constantly poured into them, as well as the Passaic, and the high rate of mortality from intestinal diseases among those who have used these waters, that cannot otherwise be accounted for.—*The Sanitarian.*

The Officier de Santé is likely to be abolished by law in France. This is the lower medical qualification in that country. In a land where all who study medicine can and do qualify themselves properly for a degree, such a title is unnecessary. France has perhaps outgrown it. In this country it would perhaps be a wise thing if those who studied medicine for three years only, taking but two didactic and no regular clinical courses, held a different degree from those who had studied four or five years, provided, of course, that those of lower grade had opportunities later to qualify in the higher.

Dr. A. B. Judson, the President of the "Orthopedic" Association, which formed part of the Congress of American Physicians and Surgeons, states that "many, even among the learned, suppose that the latter part of our name is derived from the Latin word for *foot*, instead of from the Greek for *child*. This," he adds, "is the Nemesis of phonetic spelling."

Gout from Fasting.—M. Jacques, during his fifty days' fast in London, recently suffered from gout during the later period of his fast.

The Transactions of the Tenth International Medical Congress at Berlin are gradually finding their way out of the hands of the editors and printers. The proceedings of Section VIII. (Midwifery and Gynæcology) have just appeared, while those of Sections VII.A (Orthopædic Surgery) and IX. (Neurology) are on the eve of publication. Sections VII. (Surgery) and X. (Ophthalmology) are in the press. Sections XI. (Otology), XII. (Laryngology), and XIII. (Dermatology), which complete the work, are upon the way.

Ambulance System in Baltimore Needed.—The *Johns Hopkins Hospital Bulletin* says that Baltimore has no ambulance system. Accident cases and cases of severe disease are forced to rely upon the police patrol wagon, which does not furnish any adequate shelter from the sun or storm, nor good facilities for the transportation of the sick and wounded.

Georgia Medical Examining Board Bill.—According to the *Southern Medical Record* a bill will be introduced in the Georgia Legislature looking to the establishment of a Medical Examining Board in that State.

The Southern and Gynæcological Association will hold its fourth annual session in Richmond, Va., beginning Tuesday morning, November 10, 1891.

Reviews and Notices of Books.

THE POCKET ANATOMIST. Founded upon Gray. By C. HENRI LEONARD, A.M., M.D., Professor of the Medical and Surgical Diseases of Women and Clinical Gynecology, in the Detroit College of Medicine. Fourteenth Revised Edition, containing Dissection Hints and Visceral Anatomy. Detroit, Mich.: Illustrated Medical Journal Co. 1891.

THIS is a very compact little book of nearly three hundred pages, conveniently arranged and excellently illustrated. These illustrations are photo-reproductions of those of Gray, and are well printed on glazed paper, showing all the parts with great distinctness. The anatomical descriptions are concise but clear. The pronunciation of the different terms needs revision, for students ought not to be misled by such accentuation as clitori'dis, introi'tus, pterygoide'us, mastoide'us, etc. However, the author in this respect is no greater sinner than the compilers of some medical dictionaries that ought to be authorities. That the book is a useful one and meets a want is evidenced by the fact that this is the fourteenth edition. As a convenient little work of reference its utility would be enhanced by a more copious index.

BACTERIA AND THEIR PRODUCTS. By GERMAN SIMS WOODHEAD, M.D. Edin., Director of the Laboratories of the Conjoint Board of the Royal College of Physicians and Surgeons; formerly Research Scholar of the Honorable Grocers' Company. With Twenty Photo-micrographs, and an Appendix Giving a Short Account of Bacteriological Methods, and a Diagnostic Description of the Commoner Bacteria. New York: Scribner & Welford. 1891.

AN enormous bacteriological literature has grown up within the past decade, and the student who desires to pursue the subject scientifically and prepare himself for original research, is almost hampered by an embarrassment of riches when he looks around for a guide for his first steps. There have been also many popular works written about micro-organisms and their relation to disease. But we have never seen a book better adapted to the instruction of the intelligent layman, as well as to the guidance of the beginning worker in this science, than the one before us. The main part of the work deals with the phenomena of fermentation and with a description of most of the bacteria whose relation to certain diseases is now established, while in the appendix directions are given for the cultivation, staining, and diagnosis of the most important varieties of microbes. The illustrations are fairly good, serving to elucidate the already clear descriptions in the text, and withal we can recommend the book as not only instructive, but also highly interesting, to anyone who wishes a more definite idea than he now has of the science of bacteriology.

PRACTICAL PATHOLOGY AND MORBID HISTOLOGY. By HENEAGE GIBBES, M.D., Professor of Pathology in the University of Michigan; formerly Lecturer on Normal and Morbid Histology in the Medical School of the Westminster Hospital, London; formerly Curator of the Anatomical Museum, King's College, London. Illustrated with Sixty Photographic Reproductions. Philadelphia: Lea Brothers & Co. 1891.

THE student of morbid histology and bacteriology has at his hand in this neat volume of some three hundred pages, a most excellent guide, and one which, unless he be a very advanced student, he cannot afford to be without. The work is divided into four parts, the first, that of practical pathology, containing clear and precise directions in histological technique, showing how to prepare the tissues for examination, cut, stain, and mount sections, etc. The second part deals with bacteriology, with the different forms of cultivations, microscopic examination of bacteria, etc. The third part, which comprises more than half the book, treats of morbid histology. This part is illustrated with a great number of beautiful photo-micrographs in which the microscope field is reproduced with a distinctness that is really remarkable, when it is considered that they are printed on a fairly good quality of book-paper, and not on the highly polished paper that is usually employed. The fourth part contains some very practical instruction on photography with the microscope. A few more works like this of Dr. Gibbes would soon popularize histology among the profession at large, whereas now it is to a large number of physicians almost as much of a sealed book as pharmacology or botany.

ATLAS DER CYSTOSKOPIE. Von DR. EMIL BURCKHARDT, Privatdocent der Chirurgie und früherem Assistenzarzt der chirurgischen Klinik an der Universität Basel. Mit 24 Tafeln in Farbendruck. Basel: Benno Schwabe. 1891.

THIS is a series of twenty-four chromo-lithographic plates, each presenting two or three figures illustrative of the endoscopic picture of different portions of the vesical mucous membrane in health and disease. The plates are beautifully made and give a very clear idea of what the eye actually beholds in looking through the cystoscope. The illustrations depict the normal bladder, acute and chronic cystitis, prostatichy pertrophy and the consequent trabecularism of the bladder-walls, tuberculosis and various tumors of the cystic mucous membrane, calculi, foreign bodies, and wounds and fistulæ of the bladder. All of these were drawn by Dr. Burckhardt from nature, with the exception of one representing a pin in the bladder, which is after Nicoladoni. The plates are clearly printed on thick paper, and the work is one that must prove a very useful guide to all who have to do with the surgery of the bladder.

TRANSACTIONS OF THE MISSOURI STATE MEDICAL ASSOCIATION. THIRTY-FOURTH ANNUAL SESSION, 1891. Pp. 177.

THE papers cover the usual wide range of general practice, and are all creditable.

THE MOTHER'S HANDBOOK. By LEVIN J. WOOLEN, M.D., Washington, D. C. 8vo, pp. 419. Richmond, Va.: Everet Waddey Co. 1891.

THIS is a somewhat voluminous treatise on the management of children in health and disease. It is meant for household use, but is written with accuracy and with the full appreciation of what is needed in a book of this kind. It has an appendix containing articles on diseases and accidents that may suddenly happen to grown persons.

MANUEL DE MÉDECINE ANTISEPTIQUE; Applications de l'acide phénique et de ses composés. Par le DR. DÉCLAT. Paris: O. Doin. 1890.

THE name of the author will always be remembered for the great efforts he has made to bring carbolic acid before the medical profession. In this compact volume of nearly five hundred pages, he recounts his struggles and triumphs. His ideas are so generally accepted now, in one sense, that his writing is historical rather than polemic. In one sense, we say, for while there is a consonance of opinion on the general theories of antiseptic medicine, the claims which M. Déclat makes for carbolic acid are not by any means universally accepted. He reviews the history of parasiticido-medication, and follows with general rules for the application in various modes of his favorite remedy. He then passes, in alphabetical arrangement, through a list of all the common maladies and shows the therapy of the acid therein. A copious formulary is appended. It is not often that the history of any medicinal agent is so completely written up as is the case with the one under consideration. M. Déclat has rendered a distinct service to medical literature.

Des Glycosuries non Diabétiques. Par G. Halsted Boyland, Docteur en Médecine de la Faculté de Paris, etc. Pp. 91. Paris: Henri Jouve. 1891.

The author reviews the history of the clinical discovery of sugar in the urine, and then discusses the physiological relations of this phenomenon. Among the etiological factors he includes diet, cold, malaria, diphtheria, and influenza, also gastric and hepatic disorders and syphilis. Full clinical reports illustrate his various propositions. Treatment should fulfil two indications, viz.: to limit the polyuria when it exists, and to lessen the sugar. Opium he regards, on the whole, as our most reliable drug, though he has found antipyrin of service. Of course attention is to be paid to diet, hygiene, and the removal of any assignable cause. The monograph is an able study of a most interesting clinical subject. A full bibliography is given.

Étude sur l'Adénie Pseudo-Leucémie (Maladie de Hodgkin). Par Jean Crocq, fils. Pp. 81. Brussels: H. Lamertin. 1891.

The first part of the study consists of full clinical histories of one hundred and twenty-one cases, with reports of autopsies. The second part is devoted to a general discussion of the subject. A full bibliography is given, and also some excellent woodcuts of microscopic sections from various organs. Concerning the name of the disease, he shows that the malady described by Hodgkin is not exactly what goes at the present day under the name of "Hodgkin's Disease." He prefers the common term "Pseudo-Leucæmia," as best describing the affection. The Germans will prefer, he says, the latter, and the English the former, while the French will cling to "Adénie." The author has no new views to advance.

Society Reports.

CANADIAN MEDICAL ASSOCIATION.

Twenty-fourth Annual Meeting, held in Montreal, September 16, 17, and 18, 1891.

Dr. F. G. Roddick, M.D., President, in the Chair.

(Special Report to the Medical Record.)

First Day, Wednesday, September 16th.

Among the visitors present were Mr. Thomas Bryant, of Guy's Hospital, London, England, Dr. Barber, Gynecologist, of Edinburgh, and Drs. Phelps and Gibney, of New York. A much appreciated innovation of this year was the setting apart of two hours each day to a visit to the three great general hospitals, the Montreal, the Notre-Dame, and the Hôtel-Dieu; at the latter institution Dr. Hingston performed an excision of the head of the femur of a boy, nine years of age. He also gave an address on the diagnosis of abdominal tumors.

Malaria.—Dr. Bray, of Chatham, opened the afternoon session with a paper on "Malaria." His views of its etiology were that the disease was due to a micro-organism, the placidium malarii in the blood which were taken into the system either by the respiratory or by the digestive tracts; three things were necessary for their production, namely: heat, moisture, and vegetable decomposition. Their presence in the alimentary tract gave rise to dysentery, which can only be cured by clearing out the intestines and giving quinine. The reply to the question why we have it in winter, when the decomposition of vegetation is arrested, is that there is a supply of the microbe organism stored up in the earth and drinking-water, and even the human body. In accordance with the law of all germs, they may remain quiescent as long as the constitution of their host is vigorous, but rapidly develop when the system is run down. This also explains why people may develop an attack of malaria thousands of miles away from a malarious district. Sudden changes of temperature favor an attack. He endeavored to explain the various types, such as quartan, tertian, etc., by the strength of the virus, which varied according to the age of the virus and the time of the year. Cases of old fashioned shaking ague were rare, except in immigrants who received the full strength of the poison. It had a tendency to become milder as lands were drained and cultivated and the forests were cut down. He denied the existence of such a disease as typho malaria, but there was nothing to prevent a coincidence of the two diseases. The diagnosis could be made with quinine.

Dr. Christie, of St. John, had seen the disease break out in the Sailors' Hospital among patients who had never been in the malarial district; which led him to think the disease could be imported.

Ovariotomy in Pregnant Women.—Dr. Gardner, of Montreal, read a paper on three ovariotomies in which pregnancy existed, without in any way interfering with its progress. The first one was at three months, the second at one month, and the third at four and one-half months. He thought that this fact was important, as enabling us to deal with ovarian tumors irrespective of pregnancy.

Dr. Barber, of Edinburgh, referred to several cases of women with coexisting ovarian tumor and pregnancy, in one of which there had been torsion of the pellicle, rupture of the cysts, with peritonitis; operation was performed and the woman went to full term.

Dr. Lapthorn Smith, of Montreal, desired particularly to call the attention of practitioners to the possibility of pregnant women having small ovarian cysts and Fallopian tubes full of pus, for the reason that any rough handling of the uterus after labor, as in Crede's method, might lead to their rupture; thus causing puerperal peritonitis which would surely terminate fatally unless the abdomen were opened early and its contents washed and drained. He had only had two deaths in over five hundred confinements, and one of these he believed was due to such an accident; for irrigation and curetting and other rigorous antiseptic measures failed to produce any effect. He thought that the time was not far distant when abdominal section would always be resorted to as soon as the diagnosis of general puerperal peritonitis was made out.

Dr. Alloway, of Montreal, made some remarks upon the difference there was in different uteri with regard to their readiness to empty themselves. Some cannot be made to abort without the greatest provocation, while others will miscarry very easily. He explained this difference by the presence or absence of endometritis, and he recommended the sharp curette as the best treatment for persistent miscarriages.

In replying, Dr. Gardner strongly supported Lapthorn Smith's remarks, and he also agreed with Dr. Smith in trying early laparotomy in puerperal peritonitis, as probably one third of all cases are due to rupture of cysts. In reply to a question by Dr. Ruttan, he would not recommend interference if the tumor was discovered after labor had begun, unless it were imprisoned in the pelvis, in which case he would aspirate as the temporary proceeding.

Early Diagnosis of Pott's Disease of the Spine.—Dr. V. P. Gibney, of New York, pleaded for early diagnosis in spinal disease. Every case should be thoroughly examined and the child stripped, and if there was a single tender spot a spinal jacket should be applied. If done sufficiently early every case would be saved from deformity.

Dr. Phelps, of New York, called attention to spasmodic contraction of muscle as a symptom of bone disease in young children. He advised putting them on a hard mattress with extension and counter-extension.

Dr. Bell also preferred a plaster-of-Paris corset instead of iron supports.

Dr. Roddick was in the habit of putting a child on its

face across his knees, so as to put the spine on the stretch while the painful spot was sought for.

The President's Address.—Dr. Roddick then delivered the President's address, in which he referred to the great progress Montreal was making as a great hospital centre, laying especial stress upon the many modern improvements in the Royal Victoria. In speaking of baths and mineral springs with which Canada was so well provided, he thought their value was not sufficiently appreciated. He was not altogether in favor of the five years' course, on the ground that it might keep out able but poor young men.

Rest in the Treatment of Hip-joint Disease.—Dr. A. M. Phelps, of New York, read a paper on the mechanical treatment of hip-joint disease. He thought that it began with inflammation of the articular surface, which was followed by muscular spasms, which in turn caused injury to the joint. It was a mistake to apply passive motion. How long should a joint be fixed? Until cured. He detailed a series of experiments on dogs, in whose joints ulceration followed pressure prolonged for six weeks; but after five months of simple immobilization normal joints were not affected, the only effect being that of atrophy of the muscles. The correct treatment was rest, which was best secured in bed. He preferred extension of ten pounds for a child, and lateral traction of three pounds, drawing away the thigh-bone from the pelvis.

Dr. Bryant, of London, while agreeing in everything with Dr. Phelps, thought that the question of rest was settled long ago, and that of itself would never lead to anchylosis. The great difficulty was that many of these cases were interarticular and would surely soften, break down, and suppurate, and when there is suppuration we know that we will find diseased bone which must be removed; but in the early stage we cannot tell what the condition is, and the best treatment is immobilization continued even for years.

Dr. Hingston carried this treatment out by means of extension, counter-extension, and two long lateral splints, one for each leg, which was both cheap and effective.

Drs. Sullivan, Fenwick, and Christie were also in favor of long lateral splints.

Drs. Roddick and Phelps maintained that while the long splint was the best in bed, the Thomas, of Liverpool, splint enabled the patient to go about.

Second Day, Thursday, September 17th.

The morning session was devoted to the general discussion on the advisability of making some central city, such as Ottawa or Montreal, the headquarters of the Association. General opinion was that the most successful meetings were those which were held in Montreal, and it would be better to meet here every year. The next question taken up was that of medical education. The general opinion was that the course of study should be for five years of ten months each.

Sir James Grant, of Ottawa, made a strong address in favor of a federation of the scientific associations of the North American continent.

Mr. Bryant urged his hearers to aim at making it compulsory for medical students to have a B.A. degree, and thought there should be only one examining body for the whole of Canada.

Railway Spine.—Dr. Praeger read a paper on railway spine, detailing several cases. Those which he treated by means of extension, manipulation, and plaster jackets recovered, while those whom he treated by resection, two in number, died.

Mr. Bryant thought that operation was seldom necessary. Injuries to the vertebral articulations should be treated the same as injuries of other joints, by immobilizing them.

Sir James Grant detailed two obscure cases with thoracic and abdominal symptoms, which had resisted treatment until he discovered the cause to be situated in the spine.

Calculous Pyelitis.—Dr. Fenwick read a paper on this subject, detailing several cases, in one of whom pain was absent, although there was a stone in the kidney weighing an ounce, and in another there was no hemorrhage In one case he had opened into the pleural cavity which was at once closed, and no bad results followed.

Mr. Bryant had never been obliged to remove a kidney; it had always sufficed to open it, wash it out, and drain.

Dr. Hingston thought that such cases should be operated upon as soon as seen, no matter how desperate the condition might appear.

Dr. Shepherd was also in favor of leaving the kidney in every case after removing the stone, and washing out.

Dr. Armstrong related a case in which the symptoms were quiescent for one year and then returned. In another case pain only came on when pus ceased to flow, and disappeared when the discharge was re established.

The Pathology of Anæmia.—Dr. A. B. Macallum read a paper dealing with the pathology of simple anæmia and chlorosis. The conclusions which the author drew from his own observations were as follows: 1. That hæmoglobin is derived from the nuclear substance, chromatin, which is very abundant in hæmatoblasts. 2. That the chromatin of every cell, animal and vegetable, is an iron-holding compound. 3. That the iron of iron salts administered to anæmic patients does not go directly into hæmoglobin, if it is assimilated at all. 4. That only the chromatin which is in excess of the needs of the cellular elements of the body is converted into hæmoglobin, and, therefore, a deficiency in the formation of the latter indicates in anæmic patients a deficiency in, or a small supply of, chromatin in the system, a deficiency which prevents the proper development of the organs in chlorotic patients, bringing about the condition called hypoplasia by Virchow. 5. That the chromatins of the body are formed only in the vegetable kingdom, and that hæmoglobin is a degeneration product of them, just as hæmatoidin is a degeneration product of hæmatin or hæmoglobin. 6. That iron is not assimilated in the animal body and built up into chromatin, and its action is that of preventing the decomposition brought about by alkaline sulphides or through the agency of bacteria.

In the last conclusion the author agreed with the views of Bunge.

Appendicitis.—Dr. Cotton reported four cases of this affection, all characterized by constipation and retention of urine, high temperature, and pain and tenderness. In three of the cases he operated on the eighth day, while in the fourth the abscess broke into the bladder.

Dr. Armstrong dreaded this disease very much, and had lost several cases. He believed in operating at the end of twenty four or thirty-six hours.

Dr. Praeger was more in favor of sulphate of magnesia and of opiates.

Dr. Roddick thought that many cases got well without operation, while no operation will save some of the other cases. He had obtained marvellous effects from small doses of calomel, one-tenth of a grain every hour. This latter drug was strongly endorsed.

Interesting papers were then read by Dr. Dupuis, of Brighton, on seventy-six tumors, mostly of the breast; by Dr. Shepherd on "Cæcal Hernia Complicating an Ordinary Inguinal Hernia." In this case he cut off a piece of the cæcum while removing the sac; it was sewed up with continuous silk sutures, also Lembert suture, and the patient made a perfect recovery.

Conservative Surgery of the Eye.—Dr. Buller read a paper on this subject. He advocated leaving the sclerotic so as to form a moving stump for an artificial eye, or else to resect the optic nerve, treating the cut ends with antiseptics.

Drs. Prodfoot, Foucher, Gardner, and Osborn, of

Hamilton, took part in the discussion, the general opinion being that many cases of severe injury to the eye recovered without operation.

Dr. Alloway then read a paper advocating Schroeder's operation in preference to Emmet's in cases of lacerated cervix of long standing with cystic degeneration. His paper was illustrated with wax models.

Dr. Small read a paper on "Cancer of the Cervix Complicating Labor." The general conclusion was that it was better to wait till full term.

Dr. Wilkins then read a paper on "The Cold Bath Treatment of Typhoid Fever."

Dr. Lapthorn Smith read a paper in which he strongly advocated the A.C.E. mixture. His preference for this mixture was based on fifteen years' experience with it. Its great advantage was its safety.

On the third day the meeting adjourned from noon till two o'clock, to the Notre-Dame Hospital, where many cases were shown.

The next meeting of the Association will be held in Ottawa.

Correspondence.

OF WHAT DID SHAKESPEARE DIE?

To the Editor of the Medical Record.

Sir: The above conundrum is proposed in the Medical Record of September 26, 1891. Although the cause of Shakespeare's death is a matter of pure speculation, a consideration of the conditions incident to the occasion conveys a strong probability that the poet died of pneumonia rather than paralysis, excepting that some nervous impairment may have been a predisposing cause.

His age at death, fifty-two, is a period of life when the mortality from pulmonary diseases has definitely increased in proportion to other causes.

His death occurred during the month of April, which in England, as here, is a month of treacherous changes in temperature and weather. It affords abundant opportunities for the development of respiratory lesions.

Sometime prior to his death he passed an interval of excessive conviviality, and quite likely deep intoxication, in the companionship of congenial friends. That means, that he placed himself in a situation from which reckless personal exposure would naturally arise.

Here are three factors which favor the development of pneumonia. The legend runs that at his last drinking bout he contracted a fever, from which he died. Fevers do not come in this way. Pneumonias do.

Now, supplement these by the evidence furnished by the death-mask—granting its authenticity. The matrix from which the mask was made was undoubtedly secured within twenty four hours after death, "before decay's effacing fingers have swept the lines where beauty lingers."

Death sometimes leaves upon the face the seal that designates the manner of his work. For instance, sudden, violent death arrests the muscles in their last contraction. The soldier clutches his gun, his bent knee is rigid, while from his half parted lips the oath or battle cry seems to have just sped.

The brakeman gone to immediate death in a crush bears upon his face the imprint of his last thought, of duty, of home, or what?

The expression of lingering and wasting disease touches the physiognomy otherwise. Death stands so near, so long, that the body becomes accustomed to his presence, and he is not unwelcome. At the end his hand is often gentle, and the features betoken simply placid rest.

On the contrary, the course of pneumonia is laborious. Toward the end, the expression of the face becomes like that of one who is toiling under a burden, breathlessly and without rest. The close of life is the first pause from utter weariness and exhaustion. This characteristic pneumonic expression remains after death.

Compare the features of the Shakespearian death mask with those of the dead from pneumonia at Shakespeare's age. Their identity is scarcely mistakable. That which Mr. Carpenter has described as a "look of ineffable sadness" is the true pneumonic physiognomy. It is remarkably alike to that of one who has succumbed to complete weariness—who has been tired, painfully tired, unto death. So, summing up this testimony, a jury at the present day might reasonably return a verdict of "death from pneumonia" without venturing to "move these bones" and thus invite the curse.

"Ysica Iagn."

A DANGER IN THE USE OF COCAINE.

To the Editor of the Medical Record.

Sir: An incident that occurred in my practice yesterday forcibly recalls a remark, made to me by the late Dr. C. R. Agnew, when cocaine first came into use, to the effect that someone would yet suddenly die while under its influence. This prediction, as is well known, has been fulfilled in not a few instances through hypodermic injections and other methods of using cocaine, but I do not remember to have noticed an account of serious symptoms resulting from its cataphoric use. I beg, therefore, briefly to call attention to the possible danger that may attend this method of securing the analgesic effects of cocaine.

I was treating a patient for the removal of superfluous hairs by electrolysis, upon whom I had on several previous occasions made use of a four per cent. solution of cocaine by cataphoresis.

As this strength only partially alleviated the pain when operating upon the hairs of the upper lip and under the chin, a ten per cent. solution was substituted and a more vigorous current employed.

After waiting a few moments for the cocaine to take effect I began work, when almost immediately the patient complained of great oppression in the chest.

The face became deadly pale, followed by loss of consciousness associated with violent tremors.

These ceased, and for a moment the patient was almost pulseless and death seemed imminent. Semi-consciousness, however, soon returned, and under vigorous stimulation the heart's action gradually gained in strength, but it was several hours before she fully recovered. This experience should emphasize the necessity of great caution in resorting to the cataphoric action of electricity, and illustrates how readily absorption takes place through this method. I should certainly hesitate to again use a ten per cent. solution of cocaine with a current of even five milliamperes, the strength employed in this case.

A. D. Rockwell, M.D.

October 7, 1891.

THE FIRST HIP-JOINT AMPUTATION AGAIN.

To the Editor of the Medical Record.

Sir: I hope you will pardon me for writing again at this late date upon the above question. I did not see the Record from June 20th until September 20th, hence the long silence.

While Dr. Arnold, of Brooklyn, N. Y., is correct, as to who did the operation, still the date is not correct. As the doctor did not look at the work, I doubt it, at least.

And hence, to settle the question for years to come, and to inform those who may wish to know, I quote a part of Dr. Townsend's letter to Professor Velpeau, in his preface to vol. iii. of Velpeau's "Operative Surgery," Wood & Co., 1847.

And this accounts for my not being correct, as it is positively stated in vol. ii., as referred to before, that Dr. Mott was the first; yet before vol. iii. left the press the right man was found.

Dr. Townsend says, on page iv., vol. iii.: "It is a source

of infinite satisfaction both to Dr. Mott and myself to have an opportunity, at this late hour, of rescuing another and more important surgical claim from oblivion by the accidental acquaintance we made during the past summer with the venerable Walter Brashear, M.D., for many years an eminent planter of Attakapas, La., and a senator of that State. . . . As it is now ascertained we are indebted to Dr. Brashear for the first hip joint amputation in America which was followed with complete success. This occurred as early as the year 1806, only three years after the illustrious Larrey had revived and perfected this operation in the campaigns of Napoleon." Dr. Townsend then states that "Dr. Mott cheerfully abstracted the plume from his own honored brow and affixed it to whom it rightly belonged." And further states, "as it may doubtless become the theme of future discussion, we take the opportunity of placing here upon record a too brief account of the achievement of Dr. Brashear, as communicated in his own words."

The following is Dr. Brashear's letter :

"PHILADELPHIA, August 13, 1846.

"MY DEAR SIR: In conformity to promise I now give you a brief statement of the operation which I performed in Bardstown, Ky., in August, 1806, on the hip-joint. The subject was a boy seventeen years of age. Without assigning the cause which led to the necessity of the operation, the same was performed, after consultation with Drs. Harrison and Goodlet, and conducted in the manner following, first premising that, in absence of any knowledge of an established mode for this operation, a common-sense reasoning as to its safety and facility alone dictated the manner of performing it. Therefore an operation of the thigh in the ordinary manner was determined on, as remote from the hip-joint as circumstances might justify (in this case about mid thigh). The amputation was performed, and the arteries secured. The next step was to make an incision to and from the lower end of the bone, externally, over the great trochanter to the head of the bone, and upper part of the socket. The dissection of the bone from the surrounding muscles was simple and safe by keeping the edge of the knife resting against the bone. The bone being disengaged from its integuments at its lower extremity was then turned out at a right angle from the body, so as to give every facility in the operation to separate the capsular ligament and remove the head from its socket. After the operation nothing more than ordinary dressings were used, and in the course of a short time the patient removed to St. Louis, where he was living within a few years past.

"I am very truly yours,
"WALTER BRASHEAR.

"DR. P. S. TOWNSEND."

Hoping the above will not be considered either too late or too long,

I remain yours truly,
CHEEVER BEVILL, M.D.

WINFIELD, ARK., September 23, 1891.

THE DISPENSARY ABUSE ALWAYS WITH US.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: While the matter to which I desire to call the attention of the medical profession is by no means one which has not been discussed before, the abuse is being carried to such an extent at present that I think some remedy is called for. I refer to the free treatment of patients—especially in the large cities. A visit to one of the dispensaries or out-door departments of the hospitals or post-graduate schools in New York, will convince anyone that hundreds of patients are receiving free treatment there daily, who can well afford to pay for it. None suffer so much from this abuse as the younger members of the profession, who, after giving their services gratis for a year or two at some hospital, open an office, only to find that many of the patients who legitimately belong to them are receiving free treatment in the dispensaries, etc.

There is no profession where so much work is done for "sweet charity's sake" as in medicine, and this is quite right, but the line must be drawn somewhere, and it lies within the power of the medical press and societies to deal with this question. The remedy, I fear, has not yet been discovered, but as a possible step in that direction I would suggest that, before any case is treated at these places, the patient must present a certificate from a reputable minister or physician, or from some public or private charitable institution or society, stating that he or she is deserving of free treatment. Perhaps an expression of opinion on this point from other physicians would be of interest.

A PHYSICIAN.

NEW YORK, September 29, 1891.

Clinical Department.

DILATATION OF THE STOMACH.

BY J. L. WHITCOMB, M.D.,
NEW YORK.

ON July 7th, I was hurriedly called to see Joseph M——, a bartender, aged thirty-five. I found him sitting in a chair, bent nearly double, the perspiration running in streams down his face. I learned that he had not been feeling well for two days, but had been able to stand behind the bar until about one-half hour before I saw him. His arms were flexed on his chest. Forearms and fingers were also tightly flexed. Legs and neck were rigid. He could hardly speak, his tongue muscles seemed to be in a tonic spasm. He complained of severe pain in his stomach, arms, legs, and throat, also of formication of face and limbs. Sensation normal, pulse, 100. Temperature, 101° F. Emaciated, weighing about 130 pounds. Veins distended. I gave him about 14 minims of Magendie's solution, and had him carried to bed, as he could not walk. On physical examination, I found his lungs and heart normal. Liver rather small. On inspection, his abdomen was somewhat depressed above the umbilicus and distended below that point. On palpation no pain could be elicited; below the navel it was hard and resisting. He said it was always as "hard as a board." By placing the tips of the fingers on the abdomen and quickly pressing with first one hand and then the other, a loud splashing could be heard all over the room. By grasping the body just above the hips and shaking it, this percussion was still more marked.

On percussion, there was tympanitic resonance above the navel, extending well upward and to the left. Below the navel there was flatness to within two inches of the pubes, and extending two or three inches laterally from the median line; beyond this area the percussion-note was tympanitic. He complained of "wind" rising in his throat and stopping there, and causing him pain. He seemed to have spasms of the œsophagus, made worse by talking, and he would grasp his throat when he tried to speak. His tongue was coated white and his breath was fetid.

History.—He said he had had dyspepsia for about five years, and during that time he had vomited from one to four times a day, rarely ever missing a day. Three years ago he was in hospital and was treated for his dyspepsia, his stomach being washed out every day. While undergoing this treatment he claims he grew weaker every day, and got no better till he left the hospital. He begged me not to wash out his stomach. He says he could always eat more than three men, and could drink three or four quarts at a time. Whiskey and beer disagreed with him, and he could not use them. He says he

often has cramps in the legs and arms, and in his stomach, but never so bad as at present. His mother had a "big stomach" for years before her death.

Treatment.—Morphine hypodermatically till pain and cramps subsided. As he lived in a malarial district I gave him quin. sulph., gr. x. per diem. Also acidum carbolicum, gr. j. in pills, t.i.d. And pil. ferri, strychniæ et quiniæ, t.i.d.

Diet.—Small quantities of milk punch or egg nog and soft-boiled eggs at frequent intervals. His cramps, pain, and formication gradually subsided, and by the third day had disappeared completely. Then I stopped the morphine, and after that his bowels moved two or three times a day. The passages were horribly fetid. The urine was normal. His vomiting ceased, and flatulence also, although his breath was fetid. At the end of six days he could sit up in bed and seemed to suffer from nothing but weakness. In two or three days more he was on his feet again and around.

Remarks.—Clinically, it is well known that disorders of the stomach and intestines are often associated with muscular cramps and spasms as is seen in cholera morbus, cholera infantum, and in constipation and diarrhœa in infants, where the spasms amount often to general convulsions. In adults they are rare except in Asiatic cholera and, according to Loomis, dilatation of the stomach, the cramps being confined usually to the calves of the legs. This connection between abdominal trouble and muscular spasm has been explained by assuming that the large sympathetic ganglia situated in the abdominal cavity, being irritated, act reflexly on the vaso-motor ganglia and nerves, causing a contraction of the arteries supplying the muscles affected, the resulting anæmia being the direct cause of the spasm. It seems more rational to suppose that the anæmia is of the cord and brain, and affects the motor centres principally. Puerperal eclampsia is generally considered to be uræmic in origin, but when we consider the close relation of the uterus to the large sympathetic ganglia of the abdominal cavity, how richly that organ is supplied with sympathetic nerves, how nearly the pregnant state comes to being a pathological state in many women, and how easily the finely adjusted balance of the nervous system is disturbed during pregnancy in most women in civilized countries; when we consider that in many cases of eclampsia there are no discoverable lesions of the kidneys; then we can conceive of non-uræmic eclampsia, and of muscular convulsions in pregnancy, due to the same cause as a muscular spasm in stomach or intestinal disease, namely, irritation of the sympathetic nervous system.

MATERNAL IMPRESSIONS.

By K. N. FENWICK, A.M., M.D.,

KINGSTON, ONT.

Being interested in Dr. Mason's article in the Medical Record for July 11th, and a firm believer in the influence of maternal impressions on the fœtus in utero, I would like to add my quota of evidence for this side of the argument.

Mrs. T. R—— and her husband are both of dark complexion, and their first two children were quite dark, with black hair. During the early months of her third pregnancy she wakened up one morning to find the sky of a peculiar crimson color, which made such a vivid impression that, as she expressed herself, she "thought it was the judgment day." At full term she was delivered of an albino boy. She was greatly distressed over this, and during the next pregnancy worried constantly—an albino girl was born. Then followed within two years another albino girl. The next was a boy, dark and resembling the parents, and then, at intervals of two years, two more albino girls, making five albinos in a family of eight children.

A few years ago I was consulted by a woman for some pleuritic pain, and noticed that she had marks on one side of her nose and chin like the effect of a gunpowder explosion. I offered to remove these points when she got better, but found that she was born with them. She said her mother had suffered from a gunpowder explosion during the early months of her pregnancy, and that the daughter was born with marks exactly resembling her mother's.

Another patient was during her pregnancy in the habit of looking out of the window at laborers excavating the street drain, and one of these had a hook attached to the stump of his right arm which had been amputated at the elbow. She was of a very nervous and sympathetic nature. Her child when born presented a right arm ending in a stump at the elbow exactly like that of the laborer who had excited so much sympathy in the mother.

How can these cases be explained by coincidence?

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 4, 1891, to October 10, 1891.

Alexander, Charles T., Colonel and Chief Medical Purveyor. Relieved from duties of Attending Surgeon and Examiner of Recruits in New York City, and assigned to the charge of the medical purveying depot in that city.

Forwood, William H., Surgeon. Granted leave of absence for one month, on account of sickness.

Banister, John M., Assistant Surgeon. Granted leave of absence for four months.

Suter, William N., Assistant Surgeon. Granted leave of absence for one month, to take effect on or about October 15, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 10, 1891.

Dickson, S. H., Surgeon. Ordered to Marine Barracks, Washington, D. C.

Magruder, A. F., Surgeon. Detached from Marine Barracks, Washington, D. C.

Ferebee, N. McP., Surgeon. Ordered to the Atlanta.

Drennan, M. C., Surgeon. Detached from the Atlanta.

Tryon, J. R., Surgeon. Ordered to the Chicago.

Walton, J. C., Medical Inspector. Detached from the Chicago and granted six months' leave.

Keeney, J. F., Passed Assistant Surgeon. Detached from the Minnesota, and ordered to Naval Hospital, Brooklyn, N. Y.

Crandall, R. P., Passed Assistant Surgeon. Detached from the Naval Hospital, Brooklyn, N. Y., and ordered to the Naval Laboratory.

Boyd, Robert, Assistant Surgeon. Detached from the Marine Rendezvous, Boston, and ordered to the Chicago.

Alfred, A. R., Assistant Surgeon. Detached from the Fern, and ordered to the Kearsarge.

Gates, M. F., Assistant Surgeon. Detached from the Kearsarge, and ordered to the Fern.

Ames, Howard E., Surgeon. Ordered as Delegate to the Public Health Association, Kansas City, Mo., October 20, 1891.

North, James H., Assistant Surgeon. Resignation accepted, September 8, 1891.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 10, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	52	18
Scarlet fever	61	11
Cerebro-spinal meningitis	2	5
Measles	27	4
Diphtheria	78	14
Small-pox	1	0
Varicella	0	0
Pertussis	1	7
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

Poisoning by Wild Parsnips.—Cases are reported from time to time of poisoning by eating wild parsnip. Dr. Frederick B. Power, of Madison, Wis., has been investigating these and similar cases (*Pharmaceutische Rundschau*, July, 1891), and finds that it was not the wild parsnips (*Pastinaca sativa*, Lin.), but the water hemlock or spotted cowbane (*Cicuta maculata*, Lin.), the eating of which gave rise to the poisonous symptoms.

Inebriety Legally Disqualifies the Physician.—The Secretary of the State Board of Health of Iowa announces he is convinced habitual drunkenness constitutes "palpable evidence of incompetency," as the law reads, and therefore the physician bound by inebriety should be shorn of his certificate entitling him to practice in that State.—*The Medical Age*.

The Pasteur Institute in Buenos Ayres.—The report of this institution shows that 828 patients were treated there during the first three years of its existence. These embraced persons who had been bitten by dogs undoubtedly mad as well as simply suspected cases. Of the total number of patients 11 died.

An Arab Eye-Doctor in Brussels.—A number of persons in Belgium have lost their sight in consequence of maltreatment at the hands of a travelling quack, and many others have contracted granular conjunctivitis, become possessors of corneal opacities, and suffered other ills. The man, who is or claims to be an Arab, is not molested by the authorities, and is allowed to continue his destructive work in spite of earnest protests from the medical body in Brussels.

An Extra-Mundane Origin of Influenza. — Among the many ingenious hypotheses put forward to account for the origin and spread of influenza, it is interesting to observe one which approximates to a certain extent to the doctrines of those early Italian physicians who assigned a name which has the merit of vagueness and nescience—a name for which even now we are not prepared to find a better substitute. It would appear, however, that there is something still to be said for an extra-mundane origin of this mysterious affection; and the case has been well put by Mr. G. H. Willis, who adduces facts from Dr. Parsons's report to prove not only that the spread of the disease is unaffected by aërial currents, but in opposition also to Dr. Parsons's contention that it is mainly propagated along the lines of human intercourse. Mr. Willis suggests (*The Times*, July 10th) that the disease which visits so suddenly and simultaneously so many parts of the earth may take its rise in the intrusion into the atmosphere of some poisonous gas of such density as to penetrate, in spite of the law of diffusion, to the surface of the earth, over which it would necessarily tend to travel, in the main, in a westward direction, modified variously by the lower currents of the atmosphere. Such an assumption may serve to explain many of the singular facts noted in connection with the occurrence of pandemics; but it involves also the absolute abandonment of any hope that science will ever find means to prevent the disease. When sanitation has banished all specific fevers, the human race will still be prone to infection (if that term is permissible in this relation) on the large scale from sources beyond the limits of terrestrial activity.—*Lancet*, July 18, 1891.

A New Hospital.—The Duchess Eugenia Litta Bolognini has given 500,000 francs (£20,000), the proceeds of the sale of her jewels, in consequence of the death of her husband and son, to the Ospedale Maggine, Milan, with a special request that the money may be applied for the benefit of the surgical department for children.

Toxic Power of Urine as an Aid to Diagnosis.—At a recent meeting of the Academy of Medicine, Dr. Semmola, of Naples, communicated a paper on "The Poisonous Qualities of Urine adopted as an Adjunct to Diagnosis." Up to the present time, he remarked, analysis of urine had for its principal object a diagnostic end. The discovery of leucomaines and ptomaines had greatly augmented the clinical importance of the chemical composition of urine, but the research of the toxic substances contained in the renal secretion is too long and too difficult for ordinary clinical purposes to be practised in a daily round of work. What is wanted is a rapid and simple method of measuring the toxic power of urine, such as the method of Bouchard, which consists in injecting it subcutaneously into animals. What may be termed the biological analysis here replaces with advantage the complicated chemical manipulation and calculation. Dr. Semmola had carried out this plan in his practice during the past four months, and among other cases he cited two in which the recorded observations were interesting. One was a case of phlegmonous disease of the arm in an old man of seventy. The general symptoms were extremely grave, but the biological analysis of the urine was such as to warrant a favorable prognosis, and in the result this proved correct. Dr. Semmola based his hopeful view of the case on the gradual diminution in the toxic power of the renal secretion, notwithstanding the persistence for some time of the grave symptoms above indicated. In another instance he had under observation a case of pneumonia in which an infectious origin was strongly suspected. At a certain stage in the malady a complication from cerebro-spinal meningitis was feared, so pronounced and grave were the cerebral manifestations. Here also the "biological" analysis of the urine furnished useful indications. In this latter case Dr. Semmola administered iodide of potassium, which he considered an excellent therapeutic agent in certain infectious maladies.—*Lancet*.

Medical Notes in a Case of Siberian Penal Flogging of One Hundred Lashes with the Knout.—A recent number of the *Lancet* contains a paper by Benjamin Howard on this subject, which is a curious mixture of dramatic action with accurate medical observation. This writer was given the opportunity to study closely the condition and treatment of a criminal so punished by the Russian Government. The convict, male, aged thirty-two, was examined by the post-surgeon and the writer for the evidence of the presence of any organic disease. The culprit was pale and anæmic; otherwise he was in fair health. He was placed face downward on a table fourteen inches high, and fastened by straps, so that it was impossible for him to move. His entire back, buttocks, and thighs were bared. The knout, a whip with a short, thick handle of wood, had a thong twelve feet in length, terminating in three tails, each tail ending in a stout knot. The official flogger, at the word of command, brought the three tails with great skill down upon the buttocks with sharp recoil, shouting "one." This was responded to by a sub-officer, who entered the

number at the same moment in a book. Until the fifth stroke, the appearance of the parts struck was as if fifteen strips of white paper had been pasted across them, so thoroughly did the blows expel the blood at the point of contact. From this time forward blood spattered, until the whole surface of the buttock was covered with it. At the fiftieth stroke the flogger changed sides, so that the two buttocks which were alone struck were made to bear the violence equally. Before the fifty-first stroke the surgeon felt the pulse of the convict, when, if he deemed it necessary, the remaining fifty strokes would have been postponed. During the first thirty strokes, and until the skin was generally detached, the screams of the convict were all that he could make them. They gradually diminished until the flogger changed sides, when they were reawakened; but at the sixtieth stroke they subsided into groans. On being unstrapped, the patient was carried to the hospital, where his wound and himself received as much care as if he had met with an accident for which he was not responsible. On admission, the pulse was 120 and very weak; the temperature, 99.5° F. The treatment was cold-water dressing and the internal use of stimulants. The pulse, temperature, and appetite improved gradually. As to the wound, by the third day all the loose shreds of integument and cellular tissue had become gangrenous, for which antiseptic applications were applied. The continuous use of antiseptic poultices yielded a fairly clean wound by the twelfth day. Its area was fifteen inches by ten; its depth, which invaded the muscular tissue, varied from half an inch to an inch. It looked much like the wound from an exploded shell. The writer suggested skin-grafting, which was done with success. Howard, bearing in mind the alleged former fatality of flogging in the English army, inclines to attribute the smaller percentage of mortality in Siberia to the difference in the position of the culprit. In England the culprit was tied to a post—*i.e.*, he was perpendicular—while in Russia, as at Eton, his head is always lower than the heart and part flogged—*i.e.*, he is horizontal—a difference of great importance when threatened death from syncope is induced. The writer concludes with a tribute to the humanity and skill of the Siberian penal surgeon.

The Association of Surgeons to the Pennsylvania Company.—The regular annual meeting will be held in Chicago, at the Grand Pacific Hotel, October 20, 1891.

The Inter-Continental American Medical Congress.—The Committee on Permanent Organization of the Inter-Continental American Medical Congress will meet at the Lindell Hotel, St. Louis, October 14, 1891. It is intended at this meeting to, 1, adopt a constitution; 2, elect permanent officers, domestic and foreign; 3, select time and place of meeting. Members of the Anxiliary Committees of the different States are invited to be present. Charles A. L. Reed, M.D., *Chairman;* J. W. Carhart, M.D., *Secretary.*

The Mississippi Valley Medical Association will meet in St. Louis at the same time.

Mosquito Bites.—A writer in a German contemporary says that for mosquito bites he has found in his own person nothing better than ordinary soap. He resides in Africa, and always carries a small piece of soap with him on his country expeditions. If he is bitten, he makes a lather over the affected part, and allows it to dry on. The burning is at once relieved, and all pain soon ceases. The application can be repeated as often as desired.

Tapeworm in a New Rôle.—Professor Paramuchi has reported a case of puerperal fever in which a very unexpected cause was brought to light—that is to say, the putrid remains of a tapeworm in the uterus. No untoward symptoms seem to have occurred until the tenth day after delivery, when the patient became feverish and prostrate and lost her appetite. The lochial secretion was very foul. Large doses of quinine were ordered, but no effect was produced on the temperature, which the next day was 104.2° F. The uterus was consequently washed out, two catheters being used for the purpose, as a regular uterine instrument was not at hand. The outlet catheter, after discharging some very fetid fluid, was choked up by what was found to be a putrid tapeworm. This was of course removed and sublimate irrigations given, and the symptoms soon disappeared. Regarding the question of how the tapeworm came to be in the uterus, inquiries elicited the fact that a few days before her confinement the patient had been suffering from dysenteric symptoms, and, in view of her condition, had not taken any medicine. It is probable that the worm managed to migrate after delivery from the rectum to the vagina, and that there it died and became putrid.—*Lancet.*

The Pure and the Impure.—Ricord, the syphilographer, an American by birth, seems to have led such a species of double existence as to have presented differing aspects to different persons. Dr. Oliver Wendell Holmes says that he was "the Voltaire of pelvic literature—a sceptic as to the morality of the race in general, who would have submitted Diana to treatment with his specifics and ordered a dose of blue pills for the vestal virgins." Mr. Gayerre, of New Orleans, wrote in 1887 some reminiscences in which he said: "Ricord, at the time, was a bachelor, and I believe has never married. What was my astonishment, when I entered a very large bed-room, of which the walls, from the high ceilings to the floor, were covered with none but magnificent oil paintings, representing sacred subjects. At the head of the bed was a sculptured oak priedieu, on which there was a superbly illustrated copy of the Gospels that was lying open. There was a red velvet cushion to kneel on at the foot of the priedieu, surmounted by a beautifully carved ivory Christ on a gilded cross. After a little while I was led to the presence of the medical philosopher, who habitually seemed to delight in being a cynical unbeliever. Guessing at what had passed in my mind, he said, with a laugh not unmixed, I thought, with some embarrassment of manner, 'You are surprised, are you not?' 'Certainly,' I replied; 'who would not be? Faith! my first impression was that I had been introduced by mistake into the bed-chamber of the Archbishop of Paris.' 'Well! well! my friend,' he said, in a half jocose and half serious tone, 'I hear and see so many unclean things during the day that on retiring at night I like, before going to sleep, to refresh my eyes by looking round on holy objects.'"—*Medical Standard.*

THE ETIOLOGY OF ITCHING.[1]

By EDWARD BENNET BRONSON, M.D.,

PROFESSOR OF DERMATOLOGY IN THE NEW YORK POLYCLINIC.

PRURITUS, like neuralgia, like tinnitus, like photopsia or photophobia, is only a sensation, and therefore only a symptom. Though sometimes convenient to speak of it as a disease, we can call it so only by metonomy. Even when unassociated with any malady that is its obvious cause, when occurring as an idioneurosis of the skin, the symptomatic character of this sensation should still be recognized. It is the sensory manifestation of something unseen—of some morbid change unaccompanied by visible alterations. It is true, in a general way, that we speak of disease as any condition that is a departure from what is normal, from what constitutes the state of perfect health in the organism. In a literal sense, itching is dis-ease. But in the more restricted sense in which we speak of diseases in contra distinction to their symptoms, we understand by a disease an entire morbid process, which usually involves a series of morbid conditions, and constitutes as a whole a state of things that has an independent and typical character, and when named should imply a more or less complete diagnosis. In this sense itching or pruritus is not a disease. The disease is the nervous derangement involving some molecular or anatomical change that disturbs normal relations. Even evanescent itching, such as may be elicited by titillating the skin under conditions otherwise perfectly normal, is unquestionably dependent on molecular changes in the sensory nerves, which, though transitory, are for the time being abnormal, and the disturbance should logically be regarded as a disease. Practically, however, those transitory disturbances in the economy that are in a sense corrective, in that they indicate danger and suggest their own relief, and which disappear without trace of injury directly the relief is obtained, are not considered as diseases. Such a corrective disturbance occurs in natural hunger, and likewise in ordinary, or, as it might be called, natural, itching. Nevertheless, in its most aggravated and most persistent form, the proximate and only really efficient cause of the disturbance is not changed in its essential nature, but only modified in degree. Elsewhere,[2] in studying "the sensation of itching," it was sought to identify the nature of the disorder in pruritus as a condition of dysæsthesia which implies an interrupted or obstructed process as the proximate cause. When the itching becomes excessive, when the molecular interference or disorder becomes unduly exaggerated or prolonged, the nature of the proximate cause is not changed, but with it are conjoined other and secondary causes which serve as contributory factors. We are now concerned only with such pruritus as is excessive, with cases where itching either would not exist at all, or would be trifling, but for the presence of certain accessory morbid conditions. To determine what these conditions are is the object of the present inquiry.

A factor of prime importance in the production of excessive itching, and one that is nearly always present, is a state of cutaneous hyperæsthesia. Though the dysæsthesia, which I believe to be the primary and essential condition of all pruritus, may theoretically exist in excessive itching without abnormal irritability of the cutaneous nerves, practically, in the great majority of cases at least, the hyperæsthesia is present. It may be either congenital or acquired. It may be an inborn quality of the sensory nerves, or it may be incidental to some special disease, whether systemic or cutaneous. Though not necessarily accompanied by pruritus, when present it only requires the addition of some direct exciting cause to produce excessive itching. By hyperæsthesia here is meant a peculiar morbid state or property, not one in which all the senses are co-ordinately exaggerated. As a fact, in this state the more highly developed or perceptive senses are more apt to be impaired or perverted. It is an abnormal condition unfavorable to the highest functional activity of any organ. Such an hyperæsthesia is especially apt to affect those regions of the skin that are not the most highly endowed with the perceptive sense of touch. Thus it is more often manifested over the back than the anterior surfaces of the body. The arms are more subject to it than the hands. Apparently an exception to this rule exists in the case of the soles of the feet, perhaps due to the fact that an abundant sensory nervous apparatus has not here attained so high a degree of development as it has in the hands, and hence is more liable to derangement. Now, if it be true, as has been maintained, that in pruritus the sensory state is one of dysæsthesia, it is easy to understand why the presence of hyperæsthesia, such as just described, should be favorable to it. It has been demonstrated, indeed, by the æsthesiometer, that when pruritus is associated with hyperæsthesia of the surface, as in cases of eczema of a severe neurotic type, there is also well-marked hypopselaphesia, *i.e*, impairment of tactile sense.[1]

In the so-called pruriginous diseases which are attended with trophic changes in the skin, such as eczema, lichen, pemphigus, scabies, and the like, the itching is chiefly due to direct interference with involved sensory nerves, more particularly those in the epidermis; but when the irritation has been long continued the nerves would become almost necessarily more or less hyperæsthetic, and the pruritus unduly exaggerated. Often, however, the hyperæsthesia plays a more important part. In some cases of eczema, for example, the paramount symptom is the itching, which from the start is in excess of what could easily be accounted for by the inflammatory changes. Often, indeed, it is evident that but for this symptom the catarrhal disease would disappear or be insignificant, or perhaps never have occurred at all. Not an inconsiderable proportion of the cases of eczema are preceded by a prodromal stage of pruritus, and often there is reason to believe that when the eczema does occur it is only as a consequence of the scratching. So far as those chronic or subacute eczemas that occur about the genito-anal region are concerned, I believe that in the majority of cases (unless we include those that are clearly parasitic) they are secondary to a more or less prolonged pruritus. A preliminary state of cutaneous hyperæsthesia underlies all these forms of eczema, conjoined, doubtless, to a certain susceptibility to catarrhal inflammation.

A similar predisposition on the part of the sensory nerves exists in pruritus hiemalis. Associated with a motory disturbance it accounts for chronic urticaria, and for

[1] Read before the American Dermatological Association, at the Washington meeting, in September, 1891.

[2] The Sensation of Itching, MEDICAL RECORD, October 18, 1890.

[1] Compare Rendu: Des anesthèsies spontanées, Thèse de concours d'agrégation. Paris, 1875.

that excessive sensitiveness to irritating clothing or other irritating contacts in certain individuals, and partly perhaps for an unusual susceptibility to the bites and stings of insects. It may be only a temporary or a periodically recurring condition, or it may continue throughout life. It may be the temporary effect of certain systemic conditions; certain blood diseases, such as lithæmia, uræmia, diabetes mellitus, and icterus may give rise to it, or they may be the immediate cause of the pruritus either through the presence of their irritating products in the skin, or through causing derangement at the nervous centres. The hyperæsthesia that predisposes to itching may also be an incidental effect of hysteria, hypochondriasis, and various functional disturbances of the nervous system; and finally, it may be the consequence of a disturbance reflected from some distant organ or region.

In many cases the occurrence of pruritus, as well as the allied condition, urticaria, must be accounted for as the effect of what is known as "reflex irritation." That is, the pruritus is the result of sympathy of the affected skin with some focus of irritation more or less remote. It may be from an internal organ or from some other region of the skin. It is often observed that when one begins to scratch some itchy spot or a particular efflorescence of urticaria, other itchy spots or wheals immediately spring up in other places. In that common form of itching that occurs on disrobing at night, or in any form of pruritus, in fact, the moment one begins to use the nails the limits of the pruritic area seem to expand. Sometimes they advance before the hand in scratching like a wave. Again, points of irritation will suddenly arise in remote parts of the cutaneous surface. Occasionally it seems as though direct lines of communication existed between certain points of the skin far away from each other; so that when one of these is scratched or irritated, the other directly responds with a similar sense of irritation. Dr. Bulkley first called attention to this last peculiar phase of reflex irritation in the skin, in a paper[1] read four years ago before the American Dermatological Association. The fact, which may be easily verified, is especially interesting as explaining many instances in which irritative cutaneous diseases spread otherwise than *per continuitatem*. Doubtless such reflex irritation could not occur unless the nerves of the skin were more or less hyperæsthetic.

Reflex irritation is equally manifest in cases of pruritus associated with irritation interior to the skin, as in pruritus ani from ascarides in the rectum, from internal hæmorrhoids, or from urethral stricture; in pruritus vulvæ from disorders of the internal genitals of the female, or in the more generalized pruritus that is sometimes observed in pregnancy or associated with other uterine disturbances, or that may follow embarrassed digestion.

Very often the phrase reflex irritation, like the older one *metastasis*, is used with only vague apprehension of the real conditions. When pruritus or urticaria is evidently consequent upon the ingestion of irritating articles of food or medicament, it is usually attributed to a gastro-intestinal irritation of which the cutaneous effect is supposed to be an expression of sympathy—a reflected irritation. But the primary irritation may be at the nervous centres, whence it may be directly communicated to the skin. Or more directly still, the irritating substance that was ingested may be brought into the skin itself through the circulation, and come in direct contact with the sensory nerves, thus causing the pruritus. It should be borne in mind that the skin is an important emunctory organ, and when toxic matters are circulating in the body there is a natural trend toward the surface, thereby exposing the skin to irritation in a special and direct manner. Sometimes the reaction shows itself in the form of inflammation, as in the infectious exanthemata and probably in syphilis; sometimes, when the toxic matter is less virulent, the effect may be simply a pruritus or an urticaria.

[1] Clinical Notes on Pruritus, Journal of Cutaneous and Genito-urinary Diseases, December, 1887.

Thus, independently of any preliminary hyperæsthesia, the presence in the cutaneous circulation of a materies morbi, whether it be a ptomaïne, a leucomaïne, some product of imperfect oxidation, an element of the bile or of the urine, may become the direct exciting cause of pruritus, producing it in the same way as would a foreign body, a vesicle, or other trophic change in the skin.

Likewise, with regard to those regional forms of pruritus that affect the progenitalia and the anus, though reflex irritation undoubtedly often plays a very important part, there are other factors that should not be lost sight of. It is a common opinion that pruritus ani is very often associated with hæmorrhoids, but I believe this to be an error. Certainly, in the great majority of cases there is no such connection. It is doubtful, too, if it has anything to do with the portal circulation. At least cholagogue cathartics have seemed to me to have little or no influence on the trouble. Intestinal indigestion will often aggravate it, or even account for transitory attacks, and it may be due to long continued irritation of the intestinal canal from any cause. The itching from intestinal worms, especially from ascarides in the rectum, is also a well-known instance of reflex irritation. In the same way pruritus vulvæ may be the consequence of uterine or ovarian disease. It is probably more commonly so than the effect simply of leucorrhœal discharge, which, though it may cause erythema, erosion, and eczema of the progenitalia, would hardly by itself and primarily account for pruritus. But I believe that in most instances the pruritus in these situations, as well as in that which affects the scrotum, or by extension the perineum, is most apt to be the expression of a localized neurosis which may as well be the consequence of a generalized morbid condition of the economy, such as that in lithæmia, as from any disturbance in the neighboring organs. Such conditions, it is true, often tend to vitiation of the local secretions and would thus aggravate the trouble, if not, in some cases, suffice to account for it. Some of the severest cases of pruritus of the genitals, which may, too, be attended with intense inflammation, are associated with glycosuria. But in a very considerable number of the cases of pruritus in these regions the affection is chiefly and primarily dependent on a preliminary condition of hyperæsthesia, to which the natural and particular irritability of these parts, together with their peculiar tendency to perverted sensation, renders them especially subject.

Thus far, among all the predisposing causes of pruritus that have been referred to, by implication hyperæsthesia has been considered as the sole essential factor and the one invariably present where such causes exist. It has been intimated, too, that this essential factor is effective only as it is associated with the element of hypopselaphesia. When to these two is added an appropriate exciting cause, we have all the elements most conducive to the dysæsthesia of pruritus. It would seem not impossible that simple impairment of the medium of special sense, without any preliminary hyperæsthesia, may at times suffice as the predisposing cause. Such impairment may in some measure account for the pruritus of old age.

The term pruritus senilis is often used somewhat indefinitely for any persistent itching without manifest cause occurring in old people. Properly, it should only relate to what is a consequence of nutritive changes peculiar to old age. It has been regarded as due to atrophic degeneration of the cutaneous nerves, and like alopecia senilis, a direct effect of decay in the skin. Such a conjecture is not without show of reason. It is a well-known fact that in old age all the elements of the skin, including the nerves and unstriped muscular fibres, undergo atrophic changes. As a general effect of the senile marasmus, all the special senses become more or less obtunded. Regarding pruritus as being essentially a form of dysæsthesia, and considering its relation to impaired sense of touch, it is easy to see why the conditions in senile decay would be favorable to the occurrence of

itching. Similarly atrophic conditions in the eye and ear are sometimes attended with photopsia and tinnitus aurium, which would seem to have a certain analogy with cutaneous pruritus. How common photopsia is in the aged, I am unable to say, but tinnitus is said to be a not infrequent accompaniment of senile degeneration, sometimes occurring when there is complete anæsthesia of the acoustic nerve. Both these symptoms, however, are usually associated with some special derangement of mechanism or with some special irritation of the nerves involved, to which the disturbance of sense may be more or less attributable. In pruritus senilis the conditions are such as require no other excitants to produce the itching than the ordinary contact of clothing, or even changes of temperature, which usually suffice to produce pruritus only where cutaneous hyperæsthesia is present. Hyperæsthesia would hardly be produced by atrophy alone. It is probable, however, that in a large proportion of cases to which the term pruritus senilis is applied, the atrophic changes in the skin are insufficient to account for the trouble. It is very certain, indeed, that often other causes at least contribute, if they do not alone suffice, to produce it. Many of these are incidental and more or less general effects of the senile decay, such as imperfect action of the emunctories, circulation of products of imperfect oxidation, defective metabolism, all those conditions that may be summed up in the word arthritism; these undoubtedly are all potentially predisposing causes. Finally, the atrophic changes at the nerve-centres may play a part not less, and perhaps more, important than those at the periphery.

Though hitherto we have mainly considered those causes that are predisposing, incidentally many of the exciting causes have been alluded to. We have seen that these are not necessarily confined to such as act from without. Not only may irritative atrophic changes in the skin excite pruritus, but a direct irritation may be caused by abnormal elements in the circulation or be transmitted directly from deranged nervous centres. It is easy to see why trophic changes should cause pruritus, especially if seated in the epidermis. The involved nerves may be irritated by pressure, constriction, or other interference with normal function. Simply by inducing metabolic changes, the molecular movements would be disturbed with resulting perturbation of sensation. Occasionally nerves are found degenerated, though such degenerated nerves may or not be the source of the pruritus. Irritating materials in the cutaneous circulation would be somewhat less apt to excite itching directly than the agencies just cited, while such forms of pruritus as depend upon a preliminary hyperæsthesia are probably rarely absolutely spontaneous. A provoking cause must be added. It may be the slightest external contact, the touch of the clothing, a breath of air, or slightest change of temperature. In many cases of pruritus, apparently spontaneous, there is, I believe, one source of excitation of considerable moment that has commonly been overlooked. I refer to muscular action, more particularly of the arrectores pilorum. It may be associated with inflammatory irritation or not. Speaking generally, hyperkinesis is very often associated with hyperæsthesia. Such disturbances of motility as muscular spasm and contracture are not infrequent accompaniments of excessive nervous excitement. They often give rise to pain, as well as result from it. I believe that similar relations exist between disturbances of motility in the cutaneous muscles and pruritus.

It will not be denied that the hairy regions of the body are especially subject to pruritus. The extensor surfaces of the legs and arms are more often affected by it than the flexor, and doubtless chiefly for the reason that they are more abundantly supplied with hairs. Such hairy regions as the scalp, the bearded portions of the face, the genitals, and borders of the anus, are especially apt to be the seat of itching. Their hairiness is of course not the sole cause of the itching, which may be chiefly due to the influence of conditions far removed. In pruritus of the genitalia and anus the irritation, it is true, often extends well into the mucous orifices. Nevertheless its principal seat is always external and the disorder usually begins just at the margins, where the hairs are abundant. Certainly in those forms of pruritus that depend on purely local and external irritation, the hairs unquestionably play an important part. In no way can this annoying sensation be more readily produced than by tickling the sensitive hairs. This effect is well evinced in the irritation caused by the wearing of coarse woollens next to the skin. In the so-called "flannel eczema" the affection always begins about the hair-follicles. It is invariably a papular exanthem, and each papule may be seen to be transfixed by a hair. The course of events is pretty clearly the following: First, the little projecting fibres of the wool, tangling about and tickling the hairs of the skin, cause itching. Through contraction of the arrectores pilorum muscles the follicles are elevated, producing that state known as "goose-flesh." When the itching surface is scratched, as it naturally would be, the finger-nails impinging against these little elevations cause more irritation at these points, abrasion, and, finally, a papular inflammation.

Here the motory disturbance is clearly secondary to the sensory. But in other cases hyperkinesis is apparently precedent. The itching that is so common on removing the clothing and exposing the surface to the cool air, is always an accompaniment of cutis anserina. In the pruritus hiemalis, which is apparently but an exaggeration of this same effect, the same condition of the skin is generally well marked, particularly during the paroxysms of itching. Is there any connection between this effect on the motility of the skin and the pruritus other than simply an accidental one? The condition of "goose-flesh" is most commonly associated with change of temperature, more particularly with exposure to cold, and generally the only sense concerned is the temperature sense. The erection of the hairs and contraction of the skin accompanying it tend to approximate the hairs nearer together. In lower animals with hairy covering the effect of this action is to more effectually cover and protect the surface from cold. But this is not its only purpose. Bristling of the hairs, as much as erect ears, denotes alertness and vigilance for defence. Each hair is to a certain degree an organ of sense, and that it may be used to its fullest advantage it is erected and projected as far as possible to guard the animal at every point of its environment. In men the hairs are but analogues, but they retain the same properties that once gave their possessors certain advantages of defence. Horrida cutis is still the natural concomitant of shuddering, and hairs standing on end are the common signal of alarm or sudden fright. Itching is not usually associated with these contractions of the cutaneous muscles, unless the sense of contact is fairly engaged, unless the excited hairs touch something, and then only when the sense is vexed and fretted. But it is a fact that spasmodic muscular contractions of the skin may be produced by instinctive apprehension of an offensive contact. It only requires a state of hyperæsthesia to convert this apprehension into a fancied realization. It is hardly presuming too much to suppose that, given a hyperæsthetic condition of the skin, the existence of spasm of the arrectores, from whatever source it may arise, would suffice to evoke by suggestion the very same nervous impressions that are commonly and instinctively associated with it when the result of external contacts. Now, these impressions may concern either the temperature sense or the sense of touch. Hence such an inverted sequence of events as has been assumed would help explain, not only the itching of urticaria or other forms of pruritus attended with muscular spasm, but also perhaps the sense of cold in nervous rigors. As a rule, however, these two sensations do not occur simultaneously. "Goose-flesh" is not always nor usually attended with itching. The sense of temperature ordinarily dominates and excludes the sense of contact, and pruritus occurs

only when the latter sense is hyperæsthetic and the temperature sense only moderately affected. Such are the conditions in certain subjects when surfaces of the body habitually clothed are suddenly denuded, as well as under the influence of more continued cold in individuals who suffer from pruritus hiemalis.

To fully appreciate the effect of spasmodic contractions of the arrectores pilorum muscles, it is necessary to bear in mind the intimate connection of these muscles with the highly sensitive external root-sheaths of the hairs on the one hand, and with the under surface of the general epidermis on the other. Situated as they are, their energetic contraction could hardly fail to create more or less commotion in the sensory nerves of the adjacent portions of the rete, particularly in conditions of hyperæsthesia. With these considerations in view, the hypertrophy of these muscles that is such a common accompaniment of the so-called pruriginous diseases becomes a factor of much greater significance than that usually accorded to it. Doubtless, in most cases of pruritus, muscular spasm plays only the subordinate *rôle* of a contributory factor in the causation of the sensation. Usually the exciting cause is a direct irritation of the sensory nerves, either transmitted from centres interior to the skin or else developed locally as the immediate effect of nutritive or trophic changes in the skin. When the muscles become hypertrophied it is more apt to be the consequence than the cause of the pruritus, but is capable, I believe, of acting both ways, and is surely, as it seems to me, something more than merely an incidental effect of inflammation.

In connection with this subject the spasmodic condition of the cutaneous muscles in urticaria (a malady closely related to pruritus) is worth considering. It is admitted that the spastic muscular contractions are of the most essential importance in accounting for the manifestations of this affection. According to Unna,[1] the entire mechanism in the production of the wheal is to be explained as the effect of spasmodic contraction of the muscular coat of the veins, which by reducing the calibre of these vessels prevents their receiving the lymph from the adjacent tissue, where in consequence it accumulates in distended lymph-spaces, forming little lácunæ, first in the deeper parts of the skin, then higher up, and finally overflowing into the rete. Thus the localized œdema is accounted for, while the ischæmia may be partly the effect of pressure and partly of an extension of the spasm to the muscular coats of the superficial arterioles. But it does not explain the itching. The invariable association of sensory and motory disturbances in the disease must be something more than accidental coincidence. If the eruption of a wheal in nettle rash be carefully observed from the beginning, as may be done when the eruption is provoked by smartly rubbing the skin, it will be seen that the first thing to appear, after the erythematous redness excited by the irritation has continued for a little while, is the elevation of fine papules not unlike those of cutis anserina, and to all appearance produced in the same way—by spasm of the arrectores pilorum muscles. This phenomenon could be very prettily seen in a case of chronic or recurrent urticaria, in which wheals of enormous size could be produced by simple application of a cold wet sponge to the skin. First appeared the erythema, then the papular elevations that seemed to occupy the sites of hair-follicles, and then a general swelling and ischæmia gradually overspreading the entire area to which the cold had been applied. The itching begins with the appearance of the papules, and gradually grows intenser with the development of the wheal. What simpler and more reasonable explanation of the perturbed sensation than to ascribe it to the action of spastic muscular contraction affecting directly the sensory nerves?

Why a pruritic disease should at one time be attended with urticaria and at another not, we can no more explain than why a general neurotic condition should at one time manifest itself in hysteria or neuralgia, and at another in chorea. The urticarial hyperkinesis does unquestionably complicate very many pruritic affections. It is present in a great variety of conditions other than those commonly denominated urticaria toxica or urticaria chronica. It may be produced solely by external irritation, especially in individuals with peculiarly sensitive skins. Under such circumstances it may be caused by prolonged irritation from pediculi, from cimices, and from the presence in the skin of the sarcoptes scabiei. Its occurrence always denotes a condition of great cutaneous irritability. In some cases of acute papular eczema the papules will here and there have the peculiar blanched and swollen appearance that is characteristic of urticaria, and in such cases the itching is always intense; and usually it may be inferred that the eczematous element is but a secondary matter, while the most essential thing is a neuropathic disease attended with hyperæsthesia of both the sensory and motory nerves of the skin. The neuropathic predisposition may include among its effects the production of various trophic changes in the skin.

Such a tropho-neurosis may be the pathological condition in prurigo—the prurigo of Hebra, as maintained by Schwimmer and others. But that the neurosis in this disease gives rise to a particular papular lesion that is pathognomonic, I am not prepared to admit. According to my recollection of what I saw in Vienna, much less attention is paid there to any particular papules than to the general roughness and thickening of the skin occurring over the peroneal aspects of the legs and the outer surfaces of the arms, and to the persistency of pruritus in these situations. A pruritus that had existed more or less continuously from early life, and affected chiefly the above localities, invariably exempting the flexor surfaces, was pretty certainly prurigo, and when particular regions of the skin have itched more or less constantly for a lifetime, they are pretty apt to show effects of scratching in the shape of trophic lesions. Among these secondary effects of scratching and of the consequent inflammation, Auspitz numbered the so-called "prurigo papules." He regarded the disease as a sensory and motory neurosis combined, and found evidence in the pathological anatomy of exaggerated muscular action. Others have regarded the papules as closely allied to, if not identical with, the lesions of urticaria. Whether this be so or not, it is a well-known fact that urticaria plays an important part in this disease, that in its incipiency it may exist for a long time under the aspect of a persistent eruption of wheals in those situations usually affected in prurigo.

Taylor and Van Giesen, in their very interesting paper, have described the papules of prurigo as due to what the latter has termed "epidermal cysts," which are the product of liquefactive changes in the protoplasm of the rete-cells. Similar liquefactive changes have also been described in connection with the vesiculation of eczema. I am sure I have seen cases of eczema, and also severe cases of pruritus hiemalis with skin lesions, that neither on account of their location nor their general appearance could easily be distinguished from those of prurigo. Their papular character may have been due to an urticarial element not at the time apparent. It is not always easy, when trophic changes in the skin are associated with pruritus, to distinguish between what is primary and an essential part of the disease, and what is secondary and the effect of scratching. Indeed one may be over concerned about papules and vesicles and wheals and other so-called primary lesions of skin disease. The lesions are characters in which we read clinically a history and a process, but not only in the morphology of their individual efflorescences but in the arrangement, distribution, mode of evolution and involution, as well as in their associated phenomena. Every skin disease that is attended with any external manifestations at all has a physiognomy of its own that does not depend upon any one feature

[1] Beiträge zur Anatomie und Pathogenese der Urticaria simplex und pigmentosa, von Dr. P. G. Unna; Dermatologische Studien, 3. Heft, 1887. Hamburg und Leipzig.

but on the sum total of all its features. The diagnosis of eczema does not need the vesicle, nor that of scabies the cuniculus. Even granting that the "prurigo papule" were of equal importance to its disease with the vesicle and cuniculus to eczema and scabies, its discovery is by no means essential to the diagnosis. But such an equality is not granted. There is reason to believe that the prurigo papule is not absolutely essential. It cannot be denied, at least, that the severity of the itching is often out of all proportion to the trophic changes, and this is admitted by Schwimmer, who calls the disease a trophoneurosis. The papules may be insignificant or imperceptible, and yet the disease unquestionably exist. In the young child there may be no lesions other than wheals. The only absolutely essential factor thus far shown is the sensory neurosis. Whether to this there is always conjoined a motory neurosis, which is unquestionably present at the beginning, may not be positively asserted, but that such a coincidence is probable, and that whenever such motory disturbance does exist it would act as an accessory to the pruritus, appear to me reasonable propositions.

Such, then, are the pathological conditions that, as contributory factors, may be associated with pruritus. It has already been intimated that the primary or proximate cause of itching pertains to hidden molecular or dynamic changes within the sensory nervous apparatus, changes whose immediate effect has been presumed to be of the nature of a dysæsthesia, and whose only ostensible sign is the perturbed sensation.

The accessory pathological causes may be divided into predisposing and exciting, and tabulated as follows:

Predisposing Causes.—*A.* A state of cutaneous hyperæsthesia, or morbid and excessive irritability of the cutaneous nerves.

It may occur,

a. As the local expression of a general neurotic condition, either congenital or acquired, in which case the simplest excitants, such as friction of clothing or changes of temperature, may suffice to evoke the sensation; or

b. It may be due to local changes in the skin, attended with prolonged irritation of the cutaneous sensory nerves.

B. A state of hypopselaphesia, *i.e.*, a state of impaired conduction in the cutaneous nerves of tactile sense. Though usually occurring as a concomitant of hyperæsthesia of the skin, it is possible that it may exist independently of the latter, as in atrophic conditions (more particularly in pruritus senilis), when, like hyperæsthesia, it may become the predisposing cause of itching.

Exciting Causes.—*A.* Irritations conveyed to the skin from the interior of the body, either as

a. Reflex irritations; or as

b Irritations transmitted from nervous centres.

B. Direct or local irritations,

a From extraneous sources, *i.e.*, from such irritants as operate upon the surface of the skin;

b. From intra cutaneous sources, comprising

1. Lesions of trophic cutaneous diseases and their products;

2. Toxic or noxious materials deposited from the blood;

3. Effects of local nutritive disturbances, or deranged metabolism in the cutaneous sensory nerves;

4. Spastic contraction of the arrectores pilorum muscles, which though it may not of itself suffice to cause itching, is probably often associated with other causes as a contributory factor.

Gunpowder Stains of the Face.—These may be removed by painting with biniodide of ammonium, distilled water, equal parts; then with dilute hydrochloric acid, to reach the tissues more deeply affected.—*Revue de Thérapeutique.*

EXCISION OF THE SYPHILITIC CHANCRE.

By S. POLLITZER, A.M., M.D.,

NEW YORK.

LATE ASSISTANT IN DR. UNNA'S DERMATOLOGICAL CLINIQUE IN HAMBURG.

In a recent number of this journal[1] Dr. R. W. Taylor asserts very emphatically his disbelief in the utility of excision of the chancre as an abortive treatment of syphilis, and advances some excellent reasons for his view; and though I take the liberty of differing from him in this matter, it is not my intention to open a discussion on a subject which for the present has passed the stage of simple discussion. Dr. Taylor says: "The consensus of opinion among advanced syphilographers of to-day is that the operation is utterly futile, and only a small number of them . . . still cling to the opinion that syphilis may thus be suppressed;" and it is mainly to correct this misapprehension, and to combat the idea that excision of the chancre has been relegated to the limbo of useless operations, that I write these lines.

The Section of Dermatology and Syphilis, of the International Medical Congress at Berlin, last year, of which I had the honor of being one of the secretaries, contained probably as representative a body of "advanced syphilographers" as were ever brought together, and this question of the value of excision of the chancre was one of the regular subjects for debate. In my report of the proceedings of the Section to one of the journals I sum up this discussion as follows: "As to the results of excision of the chancre, there was, with the exception of Neumann (Vienna), who finds excision useless, complete unanimity. All are agreed as to the theoretical possibility of aborting syphilis by the early excision of its initial lesion. It gives the patient at least a chance for a mild syphilis, which it is incumbent on the physician to offer him." The Berlin Congress afforded the most recent general discussion on this subject, and its result will certainly not warrant the conclusions that "the consensus of opinion among advanced syphilographers is that the operation is utterly futile."

No one to-day, in cutting out a chancre, would be justified in promising his patient that the operation will prevent the syphilis from becoming general. The successful cases reported admit of two explanations. They may be explained as due to errors in the diagnosis of the chancre, or as belonging to that category of cases, which are reported occasionally, in which no symptoms of general syphilis appear, notwithstanding the occurrence of a chancre in all respects typically specific. The fact that the cell-proliferation extends along the vessels, at an early date, to a considerable distance from the chancre—a fact to which Taylor's and Van Giesen's histological studies afford a valuable confirmation—teaches us that in most cases excision of the syphilitic growth can be only partial. On the other hand, the observations of Auspitz, Unna, Pick, and many others, go to show that it is perhaps sometimes possible to remove the primary syphiloma entirely. But there are other grounds on which the operation seems rational.

The inoculation with the syphilitic virus is followed very soon—long before the chancre makes itself apparent, for at the earliest period at which we recognize it the process is already well advanced—by an inflammatory reaction. This reaction is largely protective in its nature; it is the defence which the vessels throw out against the invading poison. If the virus be feeble, or the cells of high vitality and resistance, the poison may be destroyed at its point of entry, and the infection prevented from becoming general. This we know happens frequently with the bacillus of tuberculosis. It is not uncommon to find on the post-mortem table evidence of a slight tubercular process in the lungs which has become encapsuled, and which never gave rise to a noticeable symptom during life. Whether anything like this happens in syphilis can be only a matter of conjecture,

[1] MEDICAL RECORD, July 4, 1891.

but certainly the number of well-authenticated cases of hard chancre in which no further symptoms of syphilis developed lends some color to the view that the syphilitic virus may be destroyed by purely natural processes at the point of inoculation. However this may be, we are certainly safe in assuming that the virus is delayed in its onward course by the infiltration which constitutes the chancre.

But the bacteriological researches of Bouchard and Chauveau have demonstrated the fact that the intensity of an infection is (within limits) directly dependent on the number of pathogenic organisms. If, therefore, we remove the reservoir of infection by excising the chancre promptly, we are helping the organism in its struggle against the invader, and there is at least a theoretical possibility that the intensity of the infection will be mitigated. That this is actually the case, there is a considerable amount of evidence. At the Berlin Congress, Ehlers, of Copenhagen, reported thirty-seven excisions in which the patients had remained under observation for several years. In only ten per cent. of these did severe forms of syphilis develop, whereas the proportion of cases of severe syphilis in general is about thirty-five per cent. Of fifteen cases which Jullien operated upon, three showed absolutely no signs of syphilis later, and in a fourth the disease was so attenuated—if not wholly eradicated—that the patient acquired later a second syphilitic chancre. Leloir, in a recent paper, reports several cases in which absence of all symptoms followed after excision of the chancre.

We are warranted, from these and similar cases which might be multiplied, as well as from purely theoretical considerations, in the conclusion that there is some probability that a syphilis may be aborted by the early excision of its initial lesion, and a considerable probability that its course will be rendered more benign.

The question is certainly not *res adjudicata*. What is needed in its present stage is more evidence. Altogether four hundred or five hundred cases of excision have been reported. I have no doubt that two or three times that number of operations have been made that were never published. Most of these probably were made at the time this method of treatment was first generally discussed, and in the six or eight years that have elapsed sufficient time has been afforded for a judgment of the effect of the operation in the individual cases. Physicians who have notes of such excisions and their results would do much to effect a final settlement of the value of the operation by publishing them. In preparing these notes it would be well to record the following points:

1. *a.* A precise description of the chancre with the evidence as to its specific character.

b. Number of days from the probable date of infection to the appearance of the chancre.

c. Length of period between the appearance of the chancre and its excision.

2. *a.* Was the line of incision made at a distance from the chancre?

b. Was the wound allowed to heal by granulation, or was it sutured?

c. Did the wound heal well, leaving a normal cicatrix?

3. *a.* Did secondary symptoms develop? If so,

b. What was their nature and distribution? and,

c. At what period after the appearance of the chancre did they occur?

4. Was any general antisyphilitic treatment employed?

5. *a.* Did later lesions of syphilis develop?

b. What was their character and time of appearance?

It will be possible to form a final judgment as to the value of excision of the chancre only when several thousand carefully observed cases have been recorded. Half a dozen cases with negative results prove no more than an equal number of cases in which syphilis has been aborted, and it seems to me only reasonable, in the light of all the facts, to withhold a dogmatic opinion until a sufficiently large number of cases has been collected on which to base an induction. The matter is certainly of sufficient importance to merit careful study.

21 West Fifty-second Street.

SOME CLINICAL JOTTINGS ON TWENTY CASES OF PUERPERAL ECLAMPSIA.

By EUGENE R. CORSON, B.S., M.D.,

SAVANNAH, GA.

I have had twenty cases of puerperal eclampsia out of three hundred and thirty-five cases of labor, a very remarkable percentage, and I have jotted down the points of interest and of practical bearing as they have appeared to me. Charpentier, from a table of figures from different countries of Europe, estimated the frequency of eclampsia as one case in three hundred and fifty-four confinements. The disease seems to be more frequent in tropical and semi-tropical countries, and negroes are more liable to it than whites. With the many theoretical problems which have gathered about this very interesting disease I shall have nothing to do. Few diseases have had more theories advanced both as to pathology and treatment, and yet its real ultimate cause eludes us, and we must be content with the very broad pathological idea of blood-poisoning. What this poison or poisons may be remains to be seen; it is probably the product of the peculiar and excessive tissue changes of pregnancy. The idea of its microbic origin has not been seriously entertained by the profession, despite the experiments of Blanc and Scarlini. Its true pathology is evidently a very complicated one, the complication being a very subtle action and reaction between the poisoned blood and nerve-centres. This seems to be as close as we can get at present. That there has been an advance in its treatment, both prophylactic and actual, admits of no doubt, and this is largely the result of mere empiricism; certain remedies discovered within the last fifty years have been tried and found beneficial. Advances in the future will depend, I believe, upon more accurate and extensive chemical and microscopical examinations of the blood and urine, and more sharply defined indications for the drugs and methods now employed.

The following observations are now very generally admitted:

That puerperal eclampsia assumes various forms, sometimes very mild and quickly recovering with little or no treatment, and again very severe, up to the foudroyant type, which quickly kills in spite of all treatment, mild or severe.

Again, cases which do not seem very violent succumb finally, while others, apparently hopeless, recover, due evidently to latent and reserve powers of resistance. That primiparæ, with their excitable nervous system and untried powers of endurance, suffer much more than multiparæ. That the condition and amount of the urine, the quantity of albumin, the character of the casts; its specific gravity, the amount of urea, etc., are valuable indices of the severity of the case. That the temperature and pulse are valuable guides to prognosis and treatment. That the timely recognition of the usual premonitory signs, the albuminuria, and certain nerve-symptoms, are valuable guides for prophylactic treatment; and that a judicious and prompt prophylaxis may ward off au attack otherwise fatal.

When we come to the treatment we shall find great diversity of opinion. While in Paris last summer, I took occasion to hunt up all the literature I could find on the subject, and verily it was every man for himself. The best *résumé* up to 1872 is that of Dr. A. Charpentier,[1] the substance of which may be found in the "Cyclopædia of Obstetrics and Gynecology," vol. ii., William Wood &

[1] De l'Influence des divers Traitements sur les Accès éclamptiques par le Dr. A. Charpentier. Paris, 1872.

Co., 1887. I haven't much confidence, however, in his figures, for his pet drug is chloral, and he attempts to prove too much. Still there is valuable information to be found there, and it will well repay its reading.

Amid the host of remedies, however, a few stand out prominently and hold their ground in spite of all contradictions. They are blood letting, chloroform, morphine, and chloral, and in conjunction with as rapid a delivery as possible. The better chances of the mother delivered are generally admitted; the question is with some, whether the extra shock of rapid delivery to over-excited nerve-centres does not counterbalance the good it may otherwise do. The answer to this doubt is found in complete chloroform narcosis. With this drug shock is reduced to its minimum and the convulsions as well held in check.

My own views and experience as to treatment may be briefly stated.

In the way of prophylaxis, when albuminuria, anasarca, and certain nervous symptoms point to impending trouble, I institute immediately, as far as practicable, the milk diet so successfully carried out by Tarnier, in conjunction with a regulation of the digestive organs, and a free action of the bowels, kidneys, and skin. This can usually be accomplished by simple means. The philosophy of the milk diet consists in a fully adequate nourishment of the patient with the least labor upon the digestive organs and emunctories Should this treatment fail and threatening symptoms still continue, I have great faith in the efficacy of bleeding. When convulsions are imminent I believe it will ward off an attack, and perhaps enable the patient to steer clear of it altogether. I have myself never used it in a prophylactic way, and my faith in it rests upon its value during an attack and the testimony of some who have seen its benefits. My uncle, Dr. Hiram Corson, who has published the results of three thousand and thirty six cases of labor, informs me that he has bled nine cases where convulsions threatened, and warded off the attack in every case. He, moreover, bleeds profusely. With a certain class there is abundant opportunity of carrying out this treatment; unfortunately, with the majority of patients, the physician is only called when labor has set in and the patient is already in convulsions. With the negroes in the hands of ignorant midwives, the physician is rarely called before the patient has had a number of convulsions and the disease has progressed too far to see much benefit from any treatment. This, at any rate, has been my experience.

Puerperal eclampsia is a disease the very nature of which demands prompt action; its natural tendency is from bad to worse. The physician who gets his case in the very beginning has a great advantage. Let him find out at once if labor has begun and if the case has reached term. He must decide at once to what extent he must aid and hasten delivery. The objection that forced dilatation of the cervix and the application of the forceps shock the already over-excited nerve-centres can be answered by complete anæsthesia. Under chloroform the nerve centres are put to sleep, the condition of the uterus and its contents can be thoroughly examined and ascertained, and without retarding much the pains, which will usually be found to progress steadily in spite of convulsions—provided, of course, labor has reached full term; if necessary, the cervix may be dilated and labor further hastened by forceps or version, as the case may indicate. And this anæsthesia may be kept up for several hours sufficiently to control convulsions. It puts the nerve centres in a splint till the storm blows over, and is, I believe, our most valuable remedy. It is the remedy to begin with; it enables us to grasp the case properly and understand its severity and dangers, and decide upon the plan of treatment without losing any time. If I have no chloroform I use ether to save time, but I believe chloroform to be the better drug of the two in this condition.

A tight and rigid cervix I attempt to overcome by bleeding, Barnes dilators, or the hand. As soon as the cervix permits it I deliver at once. If I have had to regret anything, it has been delay rather than too great interference. In certain cases where the convulsions have come on just at the close of labor or afterward, I have regretted delay which could easily have been overcome. And further, I believe the child's chances are better in rapid delivery. Every convulsion menaces the child.

Bleeding was the remedy years ago; the trouble was it was used indiscriminately, was too heroically employed, and it fell into disfavor. It is now coming back again, restricted and modified. For a long time I could not make up my mind to use it. I was under the impression that the system lost quite enough blood on the delivery of the placenta. During the last three years I have bled several patients with excellent results, and I have gained great confidence in the remedy when properly applied. In the severer cases of eclampsia, and where bleeding is most useful, there is apt to be but little or no hemorrhage with or following the delivery of the placenta, and I have found that one of the first indications of the approaching convulsion would be a complete suppression of the lochia. For this reason I am careful to have the nurse watch this symptom, and an unstained guard puts me on the lookout at once. This lochial suppression is accompanied by a diminished or suppressed flow of urine. I have seen the withdrawal of a pint of blood immediately start up the lochia again and tide the patient over the critical moment. The withdrawal of blood, varying in quantity from a pint to a quart, will in itself stop the convulsions for a time, at any rate; a full, bounding quick pulse will be reduced in volume and frequency, and, strange as it may seem, a weak and rapid pulse will become stronger and slower. As far as my experience goes, this latter pulse is the one most frequently met with. Even during convalescence the pulse is apt to be high. Under the same influence a hard and rigid cervix will soften, a diminished or suppressed flow of urine will start up again.

A patient in puerperal convulsions, with all its attendant conditions, will be found to require much larger doses of anodynes and narcotics to produce their effects than in ordinary cases. There is a marked lack of response to all drugs. A sufficient bleeding improves the responsiveness to drugs and diminishes the dose one-half. It is surprising how quickly and how long an ordinary dose of morphia will act after a sufficient phlebotomy. The nervous and vascular symptoms point to a spastic condition of the arterioles and capillaries, and bleeding relieves this, and the nerve centres become more responsive.

When and how much to bleed are important questions. The simpler cases will require no bleeding. I should bleed at once when the symptoms are violent—full bounding pulse, poor reaction after the convulsion, suppressed or scanty lochia, scanty urine, violent headache, rigid os, and especially if the convulsions antedate the full term of labor. A lack of responsiveness to drugs is a good indication for the lancet. If, after one bleeding, its beneficial effects die out, the pulse return to its former condition, the lochia and urine be diminished or suppressed, I bleed again, graduating the amount by the conditions of the case. If called in time and the premonitory symptoms portend trouble, I should unhesitatingly bleed as a prophylactic measure. Here, as everywhere in medicine, the physician's quick perception and good judgment must come into play.

There is an idea prevalent among medical men, and I have often heard it expressed, that morphia hypodermically is a dangerous drug in eclampsia, as it tends to diminish, if not suppress, the action of the kidneys. This has certainly not been my experience. If there is any action here, I should put it in the opposite direction. I believe morphia to be a most valuable drug here, supplementing chloroform, putting the nerve-centres in a splint till the storm blows over. A long, peaceful sleep from morphine always encourages me, and I feel justified

in buoying up the despondency of anxious relatives. The hypodermic method, further, is the ideal one, certainly, as to the exact amount of the drug given, rapidity of action, and absolute ease of administration when other avenues are cut off. I give it from one-quarter up to one grain.

Chloral, though a valuable drug, and in certain cases, perhaps, better indicated than morphine, must take a second place. If the history of the patient pointed to a marked aggravation from morphia, I should give chloral in preference, but even here I should be very sceptical. Morphine is as safe a remedy, and, moreover, you have it with you and can give it *instanter*, and save valuable time, while with chloral you must send out for it and valuable time is lost. Chloral by the rectum acts almost equally as well as by the stomach, and this is a fortunate thing in eclampsia, where the administration of drugs by the stomach is difficult, if not impossible. Where chloral is at hand and morphia not, I should give the former and not wait for the other drug. Time is so valuable in this disease that the sooner the nerve-centres are quieted the better.

I have never tried sufficiently the many other drugs which have been brought forward as valuable in eclampsia. The bromides never seemed to me quick enough to be of any value. Veratrum viride has some supporters, but it seems to me more dangerous than the above remedies and less certain in its action. Jaborandi and its alkaloid, pilocarpine, have been thoroughly tried and found wanting. I can see that belladonna, gelsemium, trinitrin, and nitrite of amyl may prove useful, but only in the milder cases. In the severe ones the system is not responsive sufficiently to allow them to act. A preliminary blood-letting may open the doors wider to them.

My idea of the treatment, then, may be summed up in a few words: Put the nerve-centres asleep as quickly and as safely as possible until the storm blows over, and deliver the patient as quickly as the obstetrical conditions will allow. Put the brain and spine asleep, and the sympathetic will be best able to work out its own salvation. With our present limited knowledge of the real pathology of eclampsia, and the drugs at our disposal, I can see no better way of helping the vital powers weather the storm.

Of my twenty cases seven were whites, with one death, and thirteen colored, with five deaths; of these one died in other hands six weeks after I delivered her, and the only case I lost after bleeding. This much greater mortality among the negroes but bears out my experience with them in a general way. They show a poor resistive power in all diseases, and succumb where the whites would pull through. Moreover, in these cases I was only called after the patient had had a number of convulsions and the disease had made considerable headway. With some the patient was virtually moribund when first seen. They are usually delivered by ignorant midwives who delay as long as possible before sending for a physician. Fifteen out of the twenty were primiparæ. In one colored case it was the seventeenth pregnancy; the patient recovered.

The one death among the seven whites occurred in a patient aged forty years, and in her twelfth pregnancy. The presentation was natural in all, and never offered any difficulty.

Of the white children I lost two, one dying on the third day. Of the thirteen colored cases I lost nine; eleven out of twenty children.

I found albuminuria more or less marked in all cases examined. In one case a trace of albumin lasted one year and then disappeared. The patient has since had two normal pregnancies and labors, and is strong and healthy. In most cases it is surprising how quickly the albumin disappears during convalescence.

Of complications, I had three lacerations of the perineum, requiring two perineorrhaphies. One colored case had intermittent fever and catalepsy; one, pneumonia; one, a good-sized uterine fibroid with marked jaundice; two had simple continued fever beginning before labor; and there was one case of puerperal mania, which passed into other hands and died six weeks after I delivered her.

I subjoin in a condensed form the salient points in these twenty cases.

Case I.—Mrs. S——, white, aged thirty, primipara. Eight convulsions before delivery and one after; anasarca and albuminuria; presentation L. O. I. Ant. First stage, eight hours: second stage, half an hour; third stage, a few minutes; a female child, dying on the third day; perineum lacerated. Treatment, chloroform and ether, forceps, and perineorrhaphy six weeks later.

This patient has since had three children without trouble.

Case II.—P. W——, mulattress, aged eighteen, primipara, unmarried; laced tightly to conceal her condition; taken in convulsions at 3 A.M. without premonitory symptoms, so far as the family noticed. First seen by me at 10 A.M., still in convulsions and wholly unconscious; stertorous breathing and large mucous râles; pulse, 160, and respirations, 44; drew off with a catheter highly albuminous urine; cervix dilated, vertex presenting; delivered by forceps, at 12.15 P.M., a large male child, dead; mother died at 3 P.M.

There was a delay of seven hours and the patient was moribund when first seen, and I had no opportunity of doing anything.

Case III.—Mrs. T——, white, aged eighteen, primipara. During the few days preceding labor had headache and a sensation of a cord drawing the head back; impaired vision; would start up in bed frightened; did not consult a physician. First convulsion at 3.30 A.M.; seen by me at 4 A.M. in the second convulsion; pulse, 160; axillary temperature normal; waters broken during first convulsion. While waiting for chloroform had her third convulsion. Under chloroform all the symptoms improved and she had no more convulsions; pulse dropped to 100, and respirations to 25; pains regular and strong.

At 8 A.M. applied forceps and delivered her in twenty minutes of a healthy female child; placenta delivered in twenty minutes; urine contained one-quarter albumin (by volume), specific gravity, 1.010; made a good recovery; urine showed a trace of albumin for one year; has since remained well and has had two normal confinements.

Here the chloroform and forceps thoroughly controlled the case.

Case IV.—P. T——, colored, aged thirty, V.-para, eighth month; when first seen was in convulsions and unconscious; cervix rigid and non-dilatable; gave chloroform and ether and applied Barnes's dilators; only after three hours could apply forceps; failing to deliver, turned and delivered by the breech a female child dead; mother never returned to consciousness and died half an hour later.

This patient had been in convulsions several hours before I saw her. Had I bled her I might have accomplished more.

Case V.—H. H——, colored, aged twenty, primipara; called at 4.30 A.M.; had had five convulsions since 10 P.M.; cervix dilated one inch, vertex presenting; gave morphia, one-third grain hypodermically; seen again at 9 A.M., two convulsions since last visit and was in convulsions when I arrived; gave ether, applied forceps at 9.05, and delivered a small female child in five minutes, asphyxiated with a knot in the cord; used artificial respiration fifty-seven minutes before the child breathed; child died next day; urine moderately albuminous, specific gravity, 1.014, loaded with phosphates and urates; no more convulsions, but the patient passed into a cataleptic trance; had malarial fever before and following labor; made a good recovery. This was a simple case, the pulse always good, and the convulsions not very severe.

Case VI.—S. V——, colored, aged eighteen, primipara, eighth month, unmarried; first seen at 1 P.M., screaming with pain in the head, and maniacal; had had several convulsions; some anasarca; no record of urine; cervix only admitted index finger. Chloroform and ether controlled the convulsions; under anæsthesia dilated cervix with the hand; applied forceps, vertex presenting, and delivered in thirty minutes a small female child, living; perineum ruptured three-fourths inch and immediately sewed up with silver wire. No convulsions after delivery and perineal tear united. Here the anæsthetic thoroughly controlled the case.

Case VII.—M. S——, colored, aged twenty, primipara; headache, anasarca, and dim vision one month before labor. First convulsion at 5 A.M.; first seen at 10 A.M.; had had two convulsions; pulse 130 and weak; gave ether, ruptured membranes, and applied forceps, vertex presenting, at 10.20, and delivered in seven minutes a well nourished female child; used artificial respiration twenty-seven minutes; double episiotomy to prevent perineal tear. Only one slight convulsion following delivery. This was also a mild case and easily controlled.

Case VIII.—R. W——, colored, aged eighteen, primipara. Found her in convulsions and unconscious; baby born four weeks and five days ago; had a hard labor but was up on the sixth day; then first noticed a swelling of the hands, face, and feet; felt very weak; before the convulsion complained of violent headache; face and body very much swollen; has had eight convulsions; urine shows a trace of albumin only; sp. gr., 1.014. Gave morphia one grain hypodermically. No more convulsions. On the day following was perfectly conscious, but has no recollection of the preceding day; tongue badly bitten; rapid convalescence.

This is a remarkable case, on account of the long interval following labor. The convulsions were typically eclampsic. Though rare, several similar cases have been published; the morphia immediately relieved.

Case IX.—Mrs. D——, white, aged twenty-five, primipara; anasarca two weeks before delivery; when seen at 2 P.M. had had twelve convulsions in the last twenty-four hours (under the care of another physician); cervix low, os tense, dilated one-half inch; vertex presenting, L. O. I. Ant. Gave chloroform, dilated cervix with fingers, applied forceps, and delivered at 2.30 P.M. an illy-nourished female child, living; placenta delivered in five minutes. No more convulsions; gradual return to consciousness. A simple case, relieved promptly by chloroform and forceps.

Case X.—H. B——, colored, aged fifteen, primipara, unmarried. Called to her at 9.10 A.M., in labor and in her fourth convulsion; vertex presenting, cervix well dilated; had complained bitterly of her head for four months; feet swollen a month, face swollen four days; no record of urine. Gave three-fourths grain morphine hypodermically; gave chloroform and delivered her in seven minutes of a living female child; did a double episiotomy to save the perineum; placenta delivered in nine minutes; one hard convulsion following labor; return to consciousness slow; still complained bitterly of pain in the head; pneumonia of right lower lobe developed on the second day. Made a good recovery.

Case XI.—A. T——, colored, aged thirty-one, IV.-para; convulsions came on at 11 P.M. with complete unconsciousness; not seen till 7.30 the next morning, and still in convulsions; cervix dilated one inch, vertex presenting; morphia, three-fourths grain hypodermically, and ether; delivered with forceps a living eight months child in a few minutes; placenta soon followed; continued the ether; pulse, 160; had two hard convulsions following delivery, the last at 8.30 P.M.; pulse gradually declined; stopped ether at 11 P.M., the patient having been under its influence three and a half hours, though not a complete narcosis; but a slight return to consciousness. Fever came on toward evening, and she died in the early morning; infant died a few hours before. In this case valuable time, eight and a half hours, was lost before I saw the patient; there was no reaction from the remedies.

Case XII.—E. S——, colored, aged eighteen, primipara; called at 3.30 P.M.; had been in labor sixteen hours and had had two convulsions. I found her in a convulsion and unconscious; cervix dilated two inches, vertex presenting; gave ether and delivered easily with forceps a male child, dead; no record of urine; gave tincture gelsemium in large doses, and finally one grain of morphia. Died the next morning.

My notes of this case are very imperfect; the patient never rallied after delivery.

Case XIII.—S. P——, aged thirty-eight, XVII.-para; sent for me in the night, believing that labor had set in; had severe pains around the waist; cervix high up and almost out of reach; no dilatation; has a fibroid in anterior uterine wall, pressing at times on the bladder and causing temporary retention. Next day drew off with catheter a large quantity of deep-colored urine, specific gravity, 1.017, and loaded with albumin; gave morphia hypodermically with relief. At 7 A.M. next day was called to her in convulsions; gave one grain morphia hypodermically; passed finger through cervix and made out the position, O. I. L. Ant.; attempted forceps, but failed; turned and delivered by the breech with great difficulty; placenta delivered in two minutes. No more convulsions; remained in a stupor the entire day; remittent fever with jaundice followed; thoroughly convalescent by second week. The morphia, ether, and rapid delivery acted well.

Case XIV.—Mrs. D——, white, aged forty, XII. para; for some time before labor complained of great pains in the back and loins; called at 10 P.M.; waters broken at 9.30; pains very violent; vertex presenting, L. O. I. Ant.; cervix soft and dilated one and one-half inch; labor progressed rapidly, patient made no fuss; during the pains the face became very red and showed great effort; rapid respirations and a choking sensation; pulse excellent; head slightly delayed on pelvic floor; at one time she complained she could not see well; head born at 12 o'clock, body followed immediately, and placenta in four minutes; uterus on compression was very sensitive, and the patient, who had borne her labor heroically, complained bitterly of the after-pains; she mentioned having always a free flow, so I gave her two drachms of ergot. I left her feeling satisfied with her condition and suspecting nothing. From press of work did not see her next day before 12 M., when I found her in a most violent convulsion and unconscious, having had three before my arrival; pupils immovable and unequal; pulse, 68; temperature, by the axilla, 104½° F.; a quart of dark urine drawn off with catheter, specific gravity, 1.012, and one-third albumin; gave ol. crotonis, gtt. iij. in butter, one grain morphia hypodermically, and chloroform, without any effect. Died sixteen hours after the birth of the child.

I have given this case more in detail because I have always felt that I might have saved the case had I bled her. The symptoms pointed to great plethora, and a timely bleeding might have saved her. At that time I was still influenced by the idea that the flow following labor was depletive enough, and so relied on the morphine and chloroform, but neither of these drugs nor the croton oil had any effect. The case was evidently of the foudroyant type. It was the only white patient I lost.

Case XV.—B. S——, mulattress, aged eighteen, primipara, had a convulsion at the birth of her dead child; seen by me at 12 M., some time afterward; she was semi-conscious, pulse, 140; seen again at 1 P.M., when I bled her from the arm, eight ounces, with evident relief; at 2.30 P.M. still complained bitterly of her head, and was in a mild delirium; bled her eight ounces more, with marked benefit. Rapid convalescence under quinine, iron, arsenic, and strychnia.

This case was a simple one, but I saw the benefit from the bleeding; it took the place of an anodyne.

CASE XVI.—Mrs. L. W. H——, aged twenty-two, primipara; sent for me in the evening preceding her labor, complaining of violent headache; face and body swollen, and urine highly albuminous; ordered hot foot-baths, and gave antipyrin and tr. gelsemium; sent for at 8 A.M.; had had two convulsions in the night, and one very violent in the morning; semi-conscious, pulse weak and 120; complains still of violent headache; vertex presenting and cervix dilated one inch; gave chloroform at 9 A.M., dilated cervix with the hand and applied forceps at 9.50 A.M.; delivered a dead female child at 10.10 A.M.; placenta in eight minutes. No further convulsions, and rapid convalescence. The case was a mild one, but a timely bleeding might have prevented any convulsions.

CASE XVII.—Mrs. C——, white, aged twenty-five, primipara; has had various ills throughout her pregnancy, suffered from strangury and nausea; saw her a week before her confinement; great œdema of pudendum; urine one-fourth albumin, specific gravity, 1.010; punctured labia with a needle and squeezed out a good deal of water; gave a saline purge and one-tenth grain saccharated calomel every two hours. The next day at 5 A.M. her first pains came on; had a dazed feeling; got up to have an action and was taken in her first convulsion at 7 A.M. Saw her soon after; gave chloroform to complete narcosis; vertex presenting and low down; cervix well dilated; forceps applied at 7.30 A.M., and delivered at 8.07 A.M. a large male child, weighing nine and one-fourth pounds; slight perineal tear to left; placenta in five minutes; a second convulsion an hour later; bled her seven ounces of very dark blood; the lochia, which had ceased, returned again after the bleeding; the pulse very rapid, 140 to 160; another convulsion at 11 A.M., and another at 12 M; gave chloroform again and bled twelve ounces, which brought down the pulse to 140, and one-fourth grain of morphia subcutaneously. Again an improvement till 7 P.M., when she had another convulsion which left her in a profound stupor; I bled her twenty ounces and gave one-fourth grain morphia subcutaneously, bringing the pulse down again; at 8 P.M. the pulse was 160 again and I bled her six ounces; drew off a quart of urine with catheter; patient passed into a quiet sleep and awoke at 12 P.M., much better and more herself; gave morphia, one-fourth grain, hypodermically, and she slept till morning; mind much better; drew off a pint and a half of urine. From this time on gradually recovered; the pulse remained over 100 for a month or more; swelling and albumin rapidly disappeared. Will soon be confined again and is in good health. This was a very severe case, and showed, I think, the value of bleeding; the morphia acted better than the chloroform.

CASE XVIII.—Mrs. M. H——, white, aged thirty, primipara; deserted by her husband, and has been under great mental strain; sent for at 3 A.M.; waters had broken; vertex presenting, and low down; cervix high up and posterior; ether given toward end of labor; at 10 P.M., as the head was passing the perineum, had a hard convulsion, a small female child almost immediately delivered; placenta in six minutes; gave chloroform at once, and a chloral and bromide mixture—chloral, 45 grains; bromide, 1½ drachm, pro dosi.

At 11 P.M. another convulsion seemed imminent, and applied chloroform suddenly and the crisis passed over. At 12 M. had a second convulsion, and bled her immediately sixteen ounces, bringing down the pulse from 140 to 130, and diminishing its volume and tension; the lochia, which had ceased just before the convulsion, were re-established; now seemed for the first time to go under the influence of the chloral. At 12 P.M. had her third convulsion; bled her twelve ounces; the lochia, which had again stopped, were re-established; gave half a grain of morphia hypodermically; drew off thirty ounces of urine by catheter, high-colored and smoky; specific gravity, 1.030, one-half albumin. At 8.45 A.M. had her fourth convulsion, the severest of all; bled her for the third time sixteen ounces, making forty-five ounces withdrawn altogether. Awoke at midnight quite rational; no more convulsions, and made an uninterrupted recovery. This patient, strange to say, was a sister of the preceding one, taken sick in an adjoining room three months afterward. The benefit of the bleeding was quite apparent; the other remedies did not seem to act until it was done.

CASE XIX.—Called at 11.30 P.M. to a colored girl, aged eighteen, primipara, seventh month, in labor, who had been in convulsions since 12 M.; had had already twelve convulsions; unconscious; vertex low down; cervix barely admitting index-finger; bled her at once one quart and two ounces, and began dilating cervix with the hand; had a hard convulsion during the phlebotomy; sent for my forceps, and by 12.15 A.M. had cervix sufficiently dilated to apply them; delivered in five minutes, without difficulty and without any tear a seven months female child, dead; left patient at 12.30, comfortable; pulse soft, regular, and 130; ordered a teaspoonful of laudanum should she have another convulsion. Seen at 10 A.M. the next day; had had five or six convulsions since last visit; gave two-thirds of a grain of morphia under the skin; drew off four ounces of urine with catheter, very high-colored; specific gravity, 1.028, one-half albumin; no more convulsions; hysterical and maniacal symptoms developed, and, losing my temper with the family, I lost my patient and she passed into other hands. She died six weeks later. Notwithstanding the fact that there was an interval of six weeks between her delivery and death, and that while in other hands other factors may have caused the fatal result, I have placed the case among my fatal ones. Convulsions as early as the seventh month are very fatal. The case had been attended in the beginning by an ignorant midwife, as usual, and I saw the patient only after she had had a number of convulsions, and the disease had made headway. And then came the difficulty of having one's orders carried out by ignorant people demoralized by a maniacal and hysterical woman. The good effects of the bleeding were very evident to me at the time.

CASE XX.—A negress, aged nineteen, II.-para.; large and plethoric; baby born six days ago; labor natural; two weeks before confinement had a good deal of mental trouble; the day before the convulsions complained of great headache. In the morning, at 7.30, had her first convulsion; lochia entirely suppressed; 8 A.M. a second convulsion; 8.30 a third convulsion; 9 o'clock a fourth convulsion; at 10 o'clock a fifth convulsion; first seen by me at 11.30, in her sixth convulsion; pulse, 120, full and strong; bled her one quart of dark blood, and gave half a grain of morphia under the skin. At 12 o'clock her seventh convulsion; bled her a pint; at 1 o'clock her eighth convulsion, but slight; the lochia returned, and there were no more convulsions; at 5 P.M., pulse, 115; urine free, dark, clear; specific gravity, 1.018, one-quarter albumin. Rapid convalescence. The value of bleeding was very evident here. The suppression of the lochia before the convulsions and their return after the bleeding was very noticeable. I regard this symptom as a valuable one, and as a good indication for the lancet.

THE DETECTION OF THE BACILLUS TYPHOSUS IN WATER.[1]

By CHARLES J. FOOTE, M.D.,

NEW HAVEN, CONN.

To detect the bacillus typhosus in water an early examination should be made. The bacillus typhosus is rarely found after two weeks from the date of infection.[2] The

[1] The experiments reported in this paper were performed in the bacteriological laboratory of the Yale Medical School.

[2] Karlinski emptied a considerable amount of a pure culture of the bacillus typhosus into a well in the yard of the Institute of Hygiene, at Munich, and was unable to detect the bacillus after two weeks (Centralblatt für Bakteriologie, Bd. vi., p. 671).

chief difficulty in detecting the bacillus in water has been due to the presence of a large number of rapidly growing water-bacteria, which liquefy the gelatine before the bacillus typhosus has time to develop. This difficulty has hitherto been met by dilution of the suspected water with sterilized water and an examination of a few drops of the mixture; by the use of some antiseptics which were thought to exert a greater restraining influence over the development of the water-bacteria than over that of the bacillus typhosus; and by the growth of the bacillus typhosus at a high temperature, since the growth of water bacteria is retarded by a temperature of 35° to 40° C., while the bacillus typhosus grows well within these limits.

Among the antiseptics employed are carbolic acid (2 per cent.) in gelatine, hydrochloric acid (.075 to 1 (per cent.), and boric acid (5 per cent.). These have all been used with varying, and usually doubtful, success.[1]

Rodet[2] has met with some success in destroying the water-bacteria by keeping bouillon which had been inoculated with the suspected water at a temperature of 40° to 45.5° C. for a few days, but admits that this method is not invariably successful.

Having had occasion to examine suspected water, I encountered so much difficulty in making a satisfactory examination that I have studied the methods of detecting the bacillus typhosus in water experimentally, first testing the growth of the bacillus typhosus and of some common water-bacteria, on various antiseptic jellies, at the temperature of the laboratory, and then on agar plates at a temperature of 35° to 40° C.

My method of testing the antiseptics consisted in making an antiseptic jelly of a desired strength, and from this jelly making plates. After the plates had hardened three stroke-inoculations were made in each plate. The stroke-inoculations were parallel with one another and about one inch apart. The middle stroke was an inoculation of the bacillus typhosus and on each side of it were stroke inoculations of two different water-bacteria. The advantages of this method are that all the bacteria are under exactly the same conditions, and it therefore readily permits us to compare side by side the rapidity of growth of the different bacteria. Furthermore, this method obviates the necessity of always making potato cultures of the colonies of the bacillus typhosus, to be sure that we are not dealing with some other bacteria resembling it.

The water-bacteria used as tests to compare with the bacillus typhosus were two kinds of green fluorescent liquefying bacteria which are very common in Connecticut water, and which grow so rapidly and liquefy the gelatine so soon that their presence is one of the chief obstacles to the detection of the bacillus typhosus in water.

In the first two experiments solutions of the antiseptics tested were made in water where this was possible, in other cases in alcohol or glycerine. It is quite possible that the amount of glycerine or alcohol present in these solutions may have influenced their antiseptic power. In all the other experiments the antiseptics which were insoluble in water were rubbed up with an equal part by weight of acacia, and water added to the desired strength, thus making an emulsion. When making small amounts of antiseptic jelly it is very difficult to attain absolute accuracy in strength, and this is not claimed for the jelly tested. The strength, however, was sufficiently accurate for the purpose in hand, as well as to show the relative value of the various antiseptics.

All of these antiseptics except β-naphthol and creolin formed a uniform antiseptic jelly, there being no appreciable precipitate or greater collection of the antiseptic in one part of the plate than in another. The alcoholic solution of β-naphthol formed a thick, white, tough precipitate when added to the nutrient gelatine, which was broken up with difficulty on shaking. This difficulty was obviated in the later experiments where an emulsion was used instead of an alcoholic solution. Creolin would not mix with the gelatine, but collected in globules over the surface of the plate. I do not regard the first and second experiments with these antiseptics of any value.

The experiments are tabulated below, and speak for themselves. While my conclusions are entirely negative regarding the use of these antiseptics for purposes of detecting the bacillus typhosus, the experiments may be of some interest as showing the effect of various antiseptics on the growth of the bacillus typhosus.

Experiment Number I.

	B. Typhosus.	Water-bacteria, Number 1.	Water-bacteria, Number 2.	Solution.
Alcohol: 1 to 6..	No growth.	No growth.	No growth.	
Glycerine: 1 to 6.	Very slight growth.	Slight growth.	Slight growth.	
Potass. Arsenite:				
1 to 3,500.....	No growth.	Good growth.	Good growth.	
1 to 6,500.....	No growth.	Good growth.	Good growth.	
Acid, Carbolic:				
1 to 200, ...	Slight growth.	Slight growth.	Slight growth.	Glycerine solution.
1 to 100.....	No growth.	Very slight growth.	Very slight growth.	
Hydronaphthol:				
1 to 13,000. ..	Fair growth.	Good growth.	Good growth.	Water and alcoholic solution.
1 to 7,000.....	Fair growth.	Good growth.	Good growth.	
Creolin:				
1 to 200.....	Fair growth.	Good growth.	Good growth.	Glycerine solution.
1 to 100.....	Fair growth.	Good growth.	Good growth.	
β-Naphthol:				
1 to 580.....	No growth.	Fair growth.	Fair growth.	Alcoholic solution.
1 to 292.....	No growth.	Fair growth.	Fair growth.	
Acid, Benzoic:				
1 to 162.....	No growth.	No growth.	No growth.	Alcoholic solution.
1 to 88.....	No growth.	No growth.	No growth.	

Experiment Number II.

	B. Typhosus.	Water-bacteria, Number 1.	Water-bacteria, Number 2.	Solution.
Olive oil: 1 to 13.	Fair growth.	Good growth.	Good growth.	
Alcohol:				
1 to 13..... .	Fair growth after 8 days.	Slight growth.	Slight growth.	
1 to 25.....	Good growth.	Fair growth.	Fair growth.	
Thymol:				
1 to 6,500.....	Very slight growth.	Good growth.	Good growth.	Alcoholic solution.
1 to 3,500.....	No growth.	Fair growth.	Fair growth.	
Acid, Salicylic:				
1 to 260... ...	Fair growth.	Fair growth.	Fair growth.	Alcoholic solution.
1 to 140.....	Very slight growth.	Very slight growth.	Very slight growth.	
Chloral:				
1 to 81.....	Very slight growth.	Fair growth.	Fair growth.	
1 to 44.....	Very slight growth.	Fair growth.	Fair growth.	
Hydrogen Peroxide:				
1 to 13.....	Fair growth.	Fair growth.	Fair growth.	*Old* preparation.
1 to 7.....	Slight growth.	Slight growth.	Slight growth.	
Camphor:				
1 to 216.....	Very slight growth.	Slight growth.	Slight growth.	Alcoholic solution.
1 to 116.....	No growth.	Slight growth.	Slight growth.	

Experiment Number III.

	B. Typhosus.	Water bacteria, Number 1.	Water-bacteria, Number 2.
Quinine Sulph.:			
1 to 130..... ..	Doubtful.	Very rapid growth.	Very rapid growth.
1 to 70.....	Doubtful.	Very rapid growth.	Very rapid growth.
β-Naphthol:			
1 to 325.....	No growth.	No growth.	No growth.
1 to 175.....	No growth.	No growth.	No growth.
Hydronaphthol:			
1 to 2,600.....	No growth.	Good growth.	Good growth.
1 to 1,400.....	No growth.	Good growth.	Good growth.
Magnesia Sulph.:			
1 to 35.....		Good growth.	Good growth.
Acacia:			
1 to 35.....	Fair growth.	Good growth.	Good growth.

EXPERIMENT NUMBER IV.

	B. Typhosus.	Water-bacteria, Number 1.	Water bacteria, Number 2.
Acid, Benzoic:			
1 to 650	Fair growth.	Good growth.	Good growth.
1 to 350	No growth.	No growth.	No growth.
Sodium Fluo-silicate:			
1 to 130	No growth.	No growth.	No growth.
1 to 70	No growth.	No growth.	No growth.
Thymol:			
1 to 2,600	Very slight growth.	No growth.	Slight growth.
1 to 1,400	No growth.	No growth.	No growth.
Potass. Arsenite:			
1 to 1,400	No growth.	No growth.	No growth.

EXPERIMENT NUMBER V.

	B. Typhosus.	Water-bacteria, Number 1.	Water-bacteria, Number 2.	
Acid, Boric:				
1 to 130	Very slight growth.	Very slight growth.	No growth.	
1 to 70	No growth.	No growth.	No growth.	
β-Naphthol:				
1 to 1,500	No growth.	No growth.	No growth.	
1 to 600	No growth.	No growth.	No growth.	
Hydronaphthol:				
1 to 325	No growth.	No growth.	No growth.	
1 to 175	No growth.	No growth.	No growth.	
Acid. Salicylic:				
1 to 325	No growth.	Very slight growth.	No growth.	
1 to 175	No growth.	No growth.	No growth.	
Antipyrin:				
1 to 130	Very slight growth.	Good growth.	Good growth.	
1 to 70	Very slight growth.	Good growth.	Fair growth.	
Sodium Fluo-silicate:				
1 to 600	Fair growth.	Slight growth.	Slight growth	
1 to 300	No growth.	No growth.	No growth.	
Acid. Lactic:				
1 to 12	Fair growth.	Fair growth.	Fair growth.	
1 to 6	No growth.	No growth.	No growth.	
Hydrogen Peroxide:				
1 to 12	No growth.	Slight growth.	Slight growth.	*Fresh* preparation.
1 to 6	No growth.	No growth.	No growth.	

EXPERIMENT NUMBER VI.

	B. Typhosus.	Water-bacteria. Number 1.	Water-bacteria, Number 2.
Nickel, Ammon. Sulph.:			
1 to 130	No growth.	No growth.	No growth.
1 to 70	No growth.	No growth.	No growth.
Cobalt, Ammon. Sulph.:			
1 to 130	No growth.	No growth.	No growth.
1 to 70	No growth.	No growth.	No growth.

It is evident from these experiments that the only antiseptics offering any advantage in favor of the bacillus typhosus are alcohol and sodium fluosilicate. I have repeatedly tested a gelatine made by adding half a cubic centimetre of alcohol to six cubic centimetres of gelatine, and find that the retardation of the growth of the water-bacteria is somewhat greater than that of the bacillus typhosus. The growth of both is delayed considerably, neither appearing much before eight days. The same may be said of a sodium fluosilicate jelly (1 to 600–1,000). After several experiments with the use of these two antiseptics in attempting to detect the bacillus typhosus in water which had previously been infected with it, I have found them of no practical value.

The examination of water for the bacillus typhosus by means of agar plates, kept at a temperature of 40° C. I have found of much greater value than the use of antiseptics. This method depends on a temperature of 40° C. to suppress the growth of water-bacteria and therefore is really a modification of Rodet's method, but was first described by Hazen and White.[1]

To test the value of this method I have performed three experiments. The first experiment consisted in making agar plates in Petri glass dishes and after they had hardened making stroke-inoculations in them of five different water-bacteria and of the bacillus typhosus. The plates were then kept in an incubator at the temperature of 36° C. and at the end of two days the following note was made:

Bacillus typhosus	Rapid growth.
Water-bacteria No. 1	Very slight growth.
Water-bacteria No. 2	Fair growth.
Water-bacteria No. 3	Fair growth.
Water-bacteria No. 4	Slight growth.
Water-bacteria No. 5	Very slight growth.

The advantage of the method was here very evident. The colonies of the bacillus typhosus were much larger and more vigorous than those of any of the water-bacteria.

The second experiment with the agar plates was very similar to the first, except that check-plates of agar were made which were kept at the temperature of the laboratory (70° F.), while corresponding plates were kept in the incubator at a temperature of 40° C. After two days the following result was obtained:

	Temp. of Room (21° C.).	Temp. of Incubator (40° C.).
Bacillus-typhosus	Fair growth.	Good growth.
Water-bacteria, No. 1	Good growth.	No growth.
Water-bacteria, No 2	Good growth.	Very slight growth.
Water-bacteria, No. 3	Good growth.	No growth.
Water-bacteria, No. 4	Good growth.	Very slight growth.
Water-bacteria, No. 5	Good growth.	No growth.

This confirms the result obtained in the first experiment.

A final practical test experiment was then made in the following way: Two sterilized pint flasks were filled with unsterilized tap water. One of these flasks was inoculated with a pure culture of the bacillus typhosus (as much as could be held on a small platinum wire loop). Two plates of agar (numbered I. and II.) were then made, each containing one cubic centimetre of the water infected with the bacillus typhosus. Two plates of agar (numbered III. and IV.) were made in the same way but were inoculated with one cubic centimetre of the tap-water which had not been infected with the bacillus typhosus. All of these plates were then put in the incubator and kept at a temperature of 40° C.

Duplicate plates to each of the above were then made of gelatine, which I have numbered I.a, II.a, III.a, IV.a. These plates were kept at the temperature of the laboratory (70° F.=21° C.).

After two days many liquid colonies were developing in all the gelatine plates, but there was none resembling the bacillus typhosus. In the agar plates the case was quite different. In Plates I. and II. there were many transparent solid colonies about the size of a pin-head, which by growing on gelatine and potato proved to be colonies of the bacillus typhosus. In Plates III. and IV. no colonies at all had developed at the end of two days.

These experiments seem to me quite conclusive and have convinced me of the great value of this method. There is one caution mentioned by Hazen and White which I have found needs to be observed, and that is that care should be taken not to mix the suspected water with the agar until the latter is quite cool, and moreover to mingle and pour out on a cold plate quickly so as to allow only the shortest possible exposure of the bacillus to the heat of the agar.

One other addition to this method has been proposed to increase still further its value. This is the addition of twenty drops of a saturated watery solution of fuchsin to each plate of agar. It has been stated that the typhoid colonies decolorize the agar in their immediate neighborhood while the colonies of other bacteria do not do this.[1] I have performed several experiments to determine the value of this decolorization for detecting the bacillus typhosus and have found it has no advantage over the plain agar. It is true that there often is a slight decolorization of the agar around the typhoid colonies, but it is frequently scarcely appreciable.

[1] Boston Medical and Surgical Journal, April 23, 1891, p. 407.

[1] Gasser: Centralblatt für Bakteriologie, Bd. viii., p. 411.

The value of the application of the method of agar plates to the detection of the bacillus typhosus in other matter than water is not so great. There are several bacteria commonly found in milk which grow at a temperature of 40° C. on agar. As a rule, however, these colonies can be distinguished from those of the bacillus typhosus by their more rapid growth, greater opacity, and more sharply defined outline. The growth of these bacteria on gelatine and potato is very different from the growth of the bacillus typhosus, some of them liquefying gelatine.

Clinical Department.

MATERNAL IMPRESSIONS.

By H. B. LEE, M.D.,

SUMMERVILLE, S. C.

DR. MASON'S case in a recent issue of the MEDICAL RECORD is so convincing that it hardly needs corroboration, but the following cases will strengthen his position.

CASE I.—Molly (colored), five months pregnant, while eating her dinner under a hedge, was terrified by a large rattlesnake falling into her lap. The snake struck at her but only buried its fangs in her apron. The child was born and is now living, aged forty years. Is a drivelling idiot, with only the lowest animal capacities. Its lower limbs are so twisted that it has to be dressed in woman's clothing, as no pair of pants could be made to fit it. Like most negroes, Molly has had a large family, most of whom are now living and are magnificent specimens of men and women.

CASE II.—Mrs. Mc——, an Irish woman, living in Atlanta, Ga, when four months pregnant was frightened by a fight between her husband and another man in the next room; she ran in just as the husband received a slap from his antagonist on the side of the neck and face, with a bloody hand, leaving the print of the four bloody fingers on his cheek and neck. Believing his throat cut she fainted. When her child was born it had the distinct mark of four bloody fingers on its neck and face. The child was living up to five years ago, when I lost sight of the family.

CASE III.—A French lady living in Charleston, S. C., and pregnant for the first time (I do not know how far gone), came into the piazza of her home to look at some green turtles a fisherman had brought for sale. She had on a little pair of bronzed slippers and touched one of the turtles with her foot, when the animal snapped at her and caught the toe of her slipper, pulling it off, and giving her a considerable fright. When the child was born it was exactly like a turtle in shape, head, body, and limbs. This monstrosity only lived a few days. The parents positively refused to allow the attending physician to preserve it. The first two cases I saw and examined, the last I was told of by a perfectly reliable physician. These facts are not merely medical curiosities, but are of vital importance to us as physicians, and I for one never fail to warn my pregnant patients to be careful what they look at. Jacob's rods were not miraculous but an application of a natural law.

HYPEREMESIS DUE TO COMPOUND HYPERMETROPIC ASTIGMATISM (EYE-STRAIN), OR TO REFLEX NEUROSES FROM THE MALE GENITAL ORGANS.

By LIEUTENANT A. E. BRADLEY,

MEDICAL DEPARTMENT, U.S.A.

(Published by authority of the Surgeon-General.)

MR A. B——, General Service Clerk, U. S. Army, was formerly a hospital steward, U. S. Army, and personally known to the writer since November, 1889. While a steward his work was such as not to demand constant application of his eyes, though he suffered at times with neuralgic (then called) headaches after too close application for even a short time.

He served with his command in the field during the Indian troubles of 1890 and 1891, and on the cessation of hostilities was discharged as a steward and appointed to the position he now occupies. His new duties kept him at his desk from nine to twelve and from one to four, and almost immediately he began to suffer with headache and impaired health. He did not at once apply for medical advice, and was not seen by the writer professionally until April 1, 1891, at which time he was treated for supra orbital neuralgia. A rest of three or four days made him again in fairly comfortable condition. On resuming his work, however, he soon began to notice a constant nausea, and this was soon followed by the vomiting of nearly all food taken, while headache became a constant symptom. An effort was made to relieve the nausea and vomiting by different remedies—tincture of nux vomica, cocaine, oxalate of cerium, Fowler's solution, etc., but without success. The tongue was clean, the appetite good; the vomiting was accomplished with little effort and resembled in nearly every respect the vomiting of pregnancy. In fact, had he been of the opposite sex one would have hardly hesitated to pronounce pregnancy the cause of the constant emesis. All medication failing, and having in the meantime become convinced that the eyes were at fault, it was decided to paralyze the accommodation and see what refractive errors existed. It should here be stated that in childhood a convergent strabismus had existed, but disappeared as maturity came on. Atropine was used, and on refracting for glasses, compound hypermetropic astigmatism of both eyes was found to exist as follows: V., R. E. $\frac{20}{80}$, L. E. $\frac{20}{60}$; V., R. E. + 1 + .50 ax. 90° = $\frac{20}{20}$; V., L. E. + 1.25 + .25 ax. 90° = $\frac{20}{20}$. Glasses were ordered accordingly on April 22, 1891. The nausea and vomiting continued unabated and the patient rapidly lost flesh, so that at this time he weighed only 130 pounds, in contrast to his usual weight, 145 or 150 pounds. All the usual remedies having been used without the least benefit, complete rest of the stomach was obtained by rectal alimentation, using predigested milk, and for ten days no food was allowed except that taken by the rectum. The nausea, however, still remained to some extent, and he was at this time, about May 1st, advised to take a short leave. He went away, and on returning was much better; had commenced taking food by the mouth, and though there was more or less nausea, vomiting did not now occur. While away he gained fifteen pounds in weight. He resumed work on May 11th, having gone on sick report April 17, 1891. His headaches have been entirely cured, and the glasses ordered have proved eminently satisfactory. His weight is now 158 pounds. Nausea continued until early in June, and then ceased.

While studying this case my attention was attracted to a short paragraph of the MEDICAL RECORD, April 25, 1891, p. 484. It is not thought that the report of this case would be complete without referring to the following points. The patient was engaged to be married to a young woman, and lived with her parents prior to his marriage. The date of the wedding was June 1st. It will be noticed that very soon after their marriage all symptoms which had been so troublesome disappeared; that marked benefit resulted from a short absence, and that some symptoms returned when he came back. Inquiry, as was surmised, brings out that while attentive to his affianced and in her presence, he, being of a passionate nature, labored under much sexual excitement, and had prolonged erections, in other words, coitus reservatus. After marriage, and being thus able to gratify his desires to their fullest extent, his nausea entirely disappeared. He admits that he began to improve immediately afterward, and in a few days was entirely well and has so remained. The paragraph alluded to is the following:

"*Relation of Stomach Disorders to Affections of the Male Genital Organs.*—Professor Peyer claims to have

demonstrated reflex neuroses of this kind in over three hundred cases. He points out the close, and frequently observed, connection between diseases of the female generative organs and the stomach, and claims that a similar relation is to be observed in the male. The principal cause of these neuroses he finds in onanism, abusus sexualis, and coitus reservatus. The symptoms relating to the stomach are atony, gastroplegia, nervous vomiting, eructations, cramps, and the secondary disturbances of these conditions. The diagnosis is oftentimes difficult, but may be made by the presence of products of chronic urethritis in the spermatic urine. Therapy is to be especially directed to relieving the local sexual disorders, and the condition of the nervous symptom.—*Volkmann's Sammlung klinischer Vortrage.*"

The writer regrets that the original article is not at his disposal. After a careful study of this case he admits that to him doubt still exists as to the cause of the hyperemesis. Was it eye-strain, or was it reflex vomiting due to the coitus reservatus, and the impression made by this condition on the nervous system? He is inclined, however, to the belief that this case was one due to the genital reflex neurosis more than to the eye-strain, the latter being merely incidental. It may be that each played an important factor, and that the hyperemesis would not have developed from either condition independently.

TURPENTINE IN POST-PARTUM HEMORRHAGE.

By B. J. WETHERBY, M.D.,

ARLINGTON, KAN.

In the MEDICAL RECORD of June 20, 1891, Dr. Alvah Newman has an article on post-partum hemorrhage, which I read with a good deal of interest, on account of having had recently two very severe cases. Among his remedies and procedures given for the control of the bleeding, I do not find turpentine, which I have come to look upon as a certain, speedy, and harmless remedy in this very trying class of cases. My method of using it is explained in the following report of the two cases mentioned above.

CASE I.—Mrs. S——, aged forty-four, mother of eighteen children, one pair of twins. Large, fleshy woman, strong as a man. No trouble in previous confinements, having never called a doctor in any of them. Her eighteenth labor occurred at full term and again no doctor was called. About an hour after the completion of the second stage severe flooding began, and a messenger was immediately despatched for a doctor. Being ten miles out of town, about two hours elapsed before I reached the bedside. I found her cold, pulseless, and speechless, lying in a bed literally soaked in blood. On making an examination I found a large, flabby uterus and a tightly adherent placenta, which I removed with great difficulty. I then saturated my handkerchief with spirits of turpentine, and swabbed out the uterus, which immediately responded to the stimulus, and contracted so vigorously as to squeeze out my hand. Not another drop of blood was lost, but the patient did not rally and in a few minutes expired, completely exsanguinated.

CASE II.—Mrs. H——, primipara, aged eighteen. Pale, anæmic woman, weighing about one hundred pounds. Labor was long and severe. She began flooding a few minutes after the child was born. The after-birth was delivered by Credé's method. The flooding became more profuse after the delivery of the placenta. I gave a hypodermic of 20 minims ergotole, followed by a drachm of fluid extract ergot by the mouth, vigorously kneaded the abdomen, and applied cold cloths over the uterus and thighs, without diminishing the hemorrhage. As the patient was rapidly sinking I hurriedly soaked my handkerchief with the turpentine and mopped out the womb, when it instantly contracted so vigorously as to squeeze out both my hand and the handkerchief, and there was no more bleeding. The slight smarting caused by the turpentine seemed to revive the patient, who shivered slightly, opened her eyes, and asked: "Doctor, what's that?" The only real discomfort she complained of was a slight smarting of the perineum and anus, caused by the excess of turpentine running over the parts—for I did not take time to measure the amount on my handkerchief. She made an excellent recovery.

I would not advise using a handkerchief if a piece of clean linen is at hand; but as time is precious, and turpentine is an excellent antiseptic, no sepsis need be feared.

A CASE OF SPONTANEOUS EXPULSION OF A LARGE URINARY CALCULUS.

By HENRY F. LEONARD, M.D.,

BOSTON, MASS.

THE patient, an American woman, aged sixty, has been confined to bed for ten years, suffering from paraplegia. During this time she has been attended by several physicians, each making a different diagnosis of her serious difficulty. The writer was called one midnight to find her suffering intensely from pain through the lower part of the abdomen and about the urinary bladder. There was constant dribbling of urine, this having been the case for the past two years, with soreness about the external genitals. Pulse, 150; temperature, 104° F.

Suppositories of morphine and belladonna were given for the local discomfort. Phenacetin for the rise of temperature.

The following morning she was more comfortable, having slept fairly well during the latter part of the night. She raised most decided objections to having a local examination. Said she was too sore to even think of it. The following day the bowels were moved by enema of warm water and oil. The temperature gradually became normal, and the acute pain left her, though some soreness and discomfort remained.

Two days after my first visit, the patient, thinking she was about to have a motion from the bowels, asked to be put on the bed-pan. After straining a little, something appeared within the vagina. This she removed with her fingers. It was a cystic calculus nearly as large as a hen's egg, its weight ten drachms, diameter two and one-fourth inches longitudinally and one and three-eighths inch laterally. The surface was comparatively smooth. On longitudinal section the outer layer was seen to be composed of uric acid, internal to this was a layer of lime oxalate, the nucleus being composed of uric acid, epithelial cells, pus, and granular matter.

It will be seen this was an alternating calculus, having for its nucleus a soft, offensive-smelling mass, around this an irregular deposit of lime oxalate, in other words a mulberry calculus, and outside this concentric rings of uric acid.

For several days after passing this stone the patient seemed to feel little or no relief; still complained of much soreness and discomfort.

There was a constant discharge of offensive, ammoniacal urine, keeping the bed wet, the patient uncomfortable, and making her a burden to herself and attendants. She could not say there was more urine dribbling away after the stone came away than there had been at any time for two years.

For several days she objected to having an examination, saying she lacked courage and was too sore; however, in a week or ten days one was made.

The external parts were somewhat swollen and inflamed, over the nates were a dozen or more small eroded spots.

A finger in the vagina detected nothing abnormal about the uterus or rectum. Anteriorly it passed into an opening, thence through a short canal, that felt as if lined with particles of sand, and into the bladder, which also

felt gritty. Upon withdrawing the finger a gush of milky fluid followed.

The bladder was washed out with a weak solution of potass permanganate. This was repeated every other day for several weeks.

After two or three washings there were no particles of grit, no discomfort during the operation, and a feeling of relief afterward.

Gradually the soreness left, so it was possible to make a careful, thorough examination, revealing a large fistulous opening into the urethra from the vagina. Through this the calculus undoubtedly found its way, coming from the bladder.

It moved along the urethra a short distance, thence through the vaginal anterior wall, into the vagina and to the outer world.

Since the calculus was passed the patient has become less nervous, sleeps well at night, eats almost anything her appetite demands, and has gained in flesh, strength, and appearance.

DENTISTRY AND SYPHILIS.

By G. G. FAUGHT, M.D.,

PHILADELPHIA, PA.

An editorial in the MEDICAL RECORD, entitled as above, suggests the publication of this article. The case here given, while unique in its character, is perhaps so only by reason of the circumstances that favored my discovery of the guilty party.

A brunette, aged nineteen, after an indefinite illness of some weeks, under the care of several physicians, without improvement, presented herself to me with the following history and symptoms: Until recently, she has enjoyed good health except for occasional attacks of indigestion, accompanied by small ulcers in the mouth. About two months ago she commenced failing in health and has continuously lost flesh, until she is now ten pounds under weight. The commencement of the attack is indefinite in character. She had occasional chills and was febrile; complained mostly of malaise, loss of appetite, and insomnia. Her physician diagnosed "malaria." Several weeks previous to this time she had had some dental work done which left the gums sore; they healed slowly, and with the commencement of the sickness the gum around the right upper canine became markedly inflamed and ulcerated. After several weeks, despite treatment, and a change of physicians, her condition was unimproved. An eruption now appeared over the chest and arms. (This was diagnosed as measles.) Ulcerations appeared on the hard palate, she also had nocturnal neuralgic pains in the temples. On examination, I found a superficial red ulcer around the right upper canine; several small grayish ulcerations on the roof of the mouth; a diffuse red pharynx with large tonsils; enlargements of the post-cervical glands, and of those at the angle of the jaw on the right side. Eruption still present on the chest and arms, having the characteristics of syphilitic roscola.

My diagnosis was syphilis, and this was confirmed by Dr. John B. Dearer, who saw the case at my request. I could not at this time believe that it was other than a case of dental inoculation, but questioned the advisability of informing the woman of the true nature of her disease. While thus delaying, a gentleman called upon me to inquire as to her progress; from the interest he manifested in her welfare, and knowing him to be one of my syphilitic patients with mouth lesions, I boldly accused him of having kissed her, which was reluctantly admitted. Their intimate relations began about the time of the dental manipulations. Here was the true key of the situation and the undoubted source of inoculation, revealed by an accident. Had anyone of her former medical advisers diagnosed the case, the dentist would have been blamed for her condition. It is interesting to note in this connection that Otis claims he has never known syphilitic inoculation to follow the kiss of affection. The man in this case denies that his was other than such a kiss, and the character and social position of the woman would incline one to believe the statement.

ŒSOPHAGOTOMY FOR THE REMOVAL OF A SILVER DOLLAR.

By J. T. FREELAND, M.D.,

BEDFORD, IND.

Œsophagotomy for the removal of foreign bodies appears to have been performed, according to Fischer, eighty times, the mortality being twenty per cent.

From these statistics it is to be seen that the operation is comparatively a rare one, not because it is so difficult but because it is seldom that foreign bodies become impacted in this situation. A case recently occurred in my practice of which the following is a brief report.

A young man, aged twenty-one, while carrying a dollar in his mouth and scuffling with some companions, accidentally let it slip down into his œsophagus, where it lodged at a point about an inch above the sterno clavicular articulation. I saw him about two hours after the accident, at which time he was in the hands of Dr. E. E. Mitchell who had made unsuccessful attempts at removing the coin by inverting him.

He was in intense pain and making constant and violent efforts at vomiting. I could not reach the coin with forceps and also failed to remove it with an improvised coin-catcher. As the man lived five miles in the country and we had no instruments with us with which to operate, the patient was put under the influence of morphine and the operation was deferred until the next day. Then, with the assistance of Drs. E. E. Mitchell and R. B. Short, the operation was performed.

The patient was anæsthetized, the head drawn back and to the right, making tense the muscles and fascia on the left side of the neck, and an incision made along the anterior border of the sterno-cleido-mastoid muscle three inches in length, the tissues were carefully divided with the blade and handle of the scalpel until the blood-vessels came in view. These were drawn to one side and the trachea to the other and the incision continued until the coin could be felt by the finger through the wall of the œsophagus which bulged into the wound. An incision was made down on the edge of the dollar and as soon as it could be seen it was grasped with a pair of forceps and the opening was enlarged until the coin could be drawn out. The only hemorrhage was from a small artery near the œsophagus, which was secured without difficulty. No sutures were taken in the œsophagus and the wound was packed with iodoform gauze which was afterward changed daily. As soon as the patient could speak it was evident from the tone of his voice that the recurrent laryngeal nerve had been divided.

The patient was supported by nutritive enemata for ten days. In dressing the wound, paroxysms of coughing would be excited, at which times air escaped freely. On the ninth day his bowels refused to retain the injected fluid and his temperature dropped to 97° F. A stomach-tube was introduced through the mouth, when such violent efforts at vomiting were excited that it had to be removed. He was allowed to rest a few minutes preparatory to introducing a tube through the œsophageal wound. While lying on his right side with the wound up it occurred to me that probably he could swallow in this position. I placed the end of the stomach tube in a cup of water and told him to suck the water through it and found to my satisfaction that he could swallow without difficulty. I am led to think that after an operation of this kind the patient can be fed from the time of the operation by placing him in a position so that the fluid will gravitate to the side of the œsophagus opposite to the incision. The patient rapidly improved and on the fifteenth day he could swallow liquid while in an upright position. A few days afterward he could eat some solid food and on the twenty-fifth he returned to his ordinary diet.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, October 24, 1891.

THE LOSS OF OLD AGE.

THE type of essay *De Senectute*, of which Cicero gave us the model, is not much affected now. Perhaps the Roman orator exhausted the sentimental and philosophic side of the subject. At any rate the view of old age which most interests moderns is not how to enjoy it but how to get and prolong it. Perhaps this is really the essential thing, since it appears as if, despite sanitation and all our modern improvements in living, old age is gradually slipping away from us.

It is true that we have immensely lessened infant mortality and extended the mean duration of life to over forty-five years. But the average number of old people is not correspondingly increased, and it is even charged that when great old age is now reached it is abnormal and the evidence of a deep-seated neurosis whose penalties are visited on succeeding generations.

The foregoing statements are not vague generalizations, but based upon carefully collected vital statistics. Sir James Crichton Brown, in a recent address on old age, states that since 1859, in Great Britain, the decline in the death-rate has been 17.5 per cent. at all ages under fifty-five, and only 2.7 at all ages above fifty-five. Between the years sixty-five and seventy-five there has actually been an increase in the death-rate.

The causes of this increment in later death-rates is attributed to cancer, heart diseases, nervous diseases, and kidney diseases.

These diseases are mainly of the degenerative class, and due to the wear and tear of modern life. This is shown by the fact that the death-rates after forty-five are less among women and less in the country than in the city.

Dr. Brown gives us the further discomforting reflection that men and women are growing old before their time. "Old age," he says, "is encroaching on the strength of manhood, and the infirmities associated with it are stealthily taking possession of the system some years earlier than they were wont to do in former generations. Deaths due simply to old age are now reported between forty-five and fifty-five years of age, and in large numbers between fifty-five and sixty, and there has been a reduction in the age at which atrophy and debility—another name for second childishness—kill those who have passed middle life. Presbyopia, or the long-sightedness of old age, in which near objects cannot be distinctly seen unless held at a considerable distance from the eye, is believed by some experienced ophthalmologists to begin, as a rule, rather earlier than it used to do. No trustworthy statistics on the subject exist, and of course general impressions ought to be received with caution, for it must be difficult to distinguish how far the early recognition of ocular failure in these days is attributable to the increased care bestowed on the eye, and how far it should be ascribed to untimely invasion, but I certainly attach great weight to the opinion of Mr. Critchett, who says, 'My own experience, now extending over a quarter of a century, leads me to think that both men and women now seek aid from glasses at an earlier period of life than their ancestors.' Very significant also is the statement of Mr. Brailey that 'people who have lived long in hot climates like India become presbyopic four or five years earlier than they would otherwise have done,' for life in a hot climate really means excessive wear and tear to a European. The ordinary age for the adoption of spectacles for reading used to be fifty; it is now, I believe, nearer forty-five."

The teeth are dropping out earlier, baldness is more prevalent, senile insanity is more common, and appears sooner than it used to do; suicide is increasing, and most suicides occur between the age of forty-five and sixty-five.

This is rather a doleful outlook, and one naturally seeks to know if Dr. Brown has a remedy for the ills he portrays. "There is," he tells us, "no short cut to longevity. To win it is the work of a lifetime, and the promotion of it is a branch of public medicine. Perchance one of these days we may have an International Congress on Old Age, with an exhibition of dotards for warning, and of hale and hearty centenarians for encouragement. At any rate you may rest assured that it is by steady obedience to the laws of health that old age may be attained, and by judicious regimen that it may be prolonged."

This is all very true, but, unhappily, it has been well known since the days of Hufeland. Perhaps the best and only thing that we can do is to teach children more earnestly the fact that to enjoy the last half of life they must take care of the first half. The maxim, "*Dum vivimus, vivamus*," is the one which above all makes old age a sickly and unhappy one.

A NEW SCHEME FOR A FOUR-YEARS' COURSE.

VARIOUS methods have been tried in order to persuade medical students to take a fourth year's course of study. The favorite one has been to offer a degree *cum laude*. None of these efforts have been very successful, however, except in throwing a little halo of factitious goodness and unobtrusive advertisement around the colleges. Medical students will never spend four years in getting a degree which can be obtained in three, unless it is obligatory, or there is manifest and material advantage to be gained.

The College of Physicians and Surgeons of Chicago proposes to graft on a fourth year to its course in a somewhat novel way. This consists of a year spent with a regular and approved medical preceptor. The regulations prescribed are as follows:

1. Non-residents may matriculate to take the first

year's course in the same manner and under the same conditions as if they proposed to take a resident course.

2. Non resident students will be required to select a preceptor satisfactory to the Secretary, and one who is willing to co-operate with the faculty in conducting the year's work, and give his certificate for the same at the end of the year.

3. Non-resident students must do the prescribed work and must make satisfactory weekly reports of progress in the manner provided by the faculty.

4. The course covers thirty weeks, and not more than five weekly reports may prove unsatisfactory without debarring the student from the credit of the course.

5. When a student can furnish evidence of having already taken the work in the prescribed non-resident course, he will be assigned an equivalent from a special course.

6. Students who have taken the non-resident course in a satisfactory manner, and have shown by the weekly examinations that they have done the work thoroughly and intelligently, will receive certificates from the Secretary, which, with the certificate of their preceptor, will be taken at this college in lieu of one year's study on a four-years' course.

The above plan will, we believe, strike everyone as being ingenious and wise. It restores, in a certain way, the old system of apprenticeship; but it has only the good features of that system, for the pupil is studying clinical medicine at a time when he is prepared to appreciate and obliged to utilize its advantages; while the preceptor is made more responsible by the consciousness that his pupil pays him and must be taught, or he will reflect discredit upon his instructions.

We shall watch the outcome of this new scheme with much interest, and hope it will prove practicable.

SWEET-OIL IN THE TREATMENT OF BILIARY COLIC.

Dr. Thomas J. Mays and Dr. Bloom, of Philadelphia, recently read a paper on "Olive-oil in the Treatment of Gall-stones. It was based on the results of a special collective investigation made by the Therapeutic Section of the Philadelphia Polyclinic Medical Society. Drs. Mays and Bloom sent a circular letter of inquiry to various physicians, and received answers from nineteen. These nineteen reported 37 cases of biliary colic treated by olive-oil, 17 other cases were gathered from medical literature, making a total of 54. An analysis of the cases shows that there were about one-third more females than males, that 2 died, and in 3 cases there were negative results. In the remaining 51 cases favorable effects were noticed. The investigators conclude that the statistics show the positive value of olive oil in the treatment of gall-stone colic.

The question arises, then, How does it act? Dr Rosenberg's experiments are quoted, showing that olive-oil is a powerful cholagogue, stimulating the flow of bile and lessening its consistency. It is thought, therefore, that this action explains the *rationale* of this method. It is further stated that cotton-seed oil is probably just as good as olive oil.

The dose used has generally been very large, ranging from a few ounces to a pint of oil in the twenty-four hours. It is thought that the larger doses are perhaps not necessary. The therapeutic inquiry, of which we have thus given an outline, is interesting and creditable to the Therapeutic Section. Such work, when carefully done, is of infinitely more practical utility than the presentation of cases and specimens, which makes up so large a part of modern Medical Society work. Yet the investigation carried out by Drs. Mays and Bloom also shows how difficult it is to secure therapeutic certainty. A study of the tabulated cases does not furnish to our mind any such happy conclusions regarding the use of sweet-oil as are drawn. It seems that in most cases the patients took oil and got better of the colic, but such colics usually get better anyway. While Rosenberg's experiments appear to show that sweet-oil is decidedly a cholagogue, Dr. Kishkin has made experiments which indicate that it is of no value in biliary colic, and that many of the concretions evacuated are only masses of oily acids. There are probably also a good many unreported cases which would show the inutility of the oil.

Furthermore, after all, the measure most needed in biliary colic is one that will prevent attacks, and very little evidence is presented to show that sweet-oil has prophylactic value.

We do not desire to belittle the value of the investigation made by Drs. Mays and Bloom, but it can hardly be admitted that sweet-oil yet occupies a solid position in the therapeutics of cholelithiasis. Further investigations may, however, corroborate the optimistic views taken by the Philadelphia investigators.

TUBERCULOSIS IN INFANTS.

For several years Professor L. Landouzy, of Paris, has called attention to what he believes the alarming predominance of tuberculosis as a cause of death in infants from birth to the end of the second year. In the *Revue de Médecine*, September, 1891, he reiterates his views, and dwells with great earnestness and force upon the need of more careful measures for the prevention of this source of infant mortality. In addition to previous statistics he cites those of the Hospital Tenon for the year 1890. During eleven months of this year there were 69 deaths among infants, and of these 15 died from tuberculosis, as proved by autopsy, while 3 others died probably from the same cause. He estimates that tuberculosis causes at least one-quarter of infant deaths, and thinks that about two thousand a year represents the deaths for the city of Paris.

Recent statistics from Kiel, published by Boltz, appear to show that the infant death-rate in that city from tuberculosis is 33.95 per cent. of the total infant mortality.

Professor Landouzy laments the fact that modern writers, even those of standard text-books, speak of tuberculosis as comparatively rare in infancy. While this is not strictly true, since Lorey gives a mortality among infants of over fifty per cent. on the total tubercular mortality of children, it is true that few authors or pathologists find tuberculosis among infants under the age of one year. All agree also that tuberculosis in children is much more frequent in the bones and lymphatics, while Landouzy asserts that it is frequently diffuse. It may well be that

the prevalence of tuberculosis in young children varies greatly in different countries and hospitals; and it is admitted that its prevalence in an extreme degree occurs chiefly in the lower classes.

Allowing, however, for local conditions and some bias of mind, it must yet be admitted that Professor Landouzy has called attention to a fact that deserves serious study from physicians. As he states, the baby is of all human beings the thing most manipulated and submitted to contact from others. It is dressed, undressed, nursed, washed, kissed, and caressed from morning till evening. Hence if the house, or rooms, or attendants have tuberculosis in any form, its danger is very great.

A great deal might be said as to the methods of prevention, but they are all summed up in the single rule, Keep the children from tuberculous attendants or infected rooms. Such directions apply with especial force to hospitals and the crowded homes of the poor.

THE QUESTION OF MEDICAL ETIQUETTE.

Our valued contemporary the New York *Times* has found time, amid its indictments of Russia and advocacy of a genuine Tammany democracy, to say a few unpleasant things about the subject of medical etiquette. This, we are told, is an awful and mysterious topic, concerning which the lay mind can only be sure of one thing, viz., that it is not common sense. The provocative of this vein of criticism was the occurrence of some trouble at the recent meeting of the Committee on the Organization of the Pan-American Medical Congress. The disturbance in question does not appear to us to have been of very great moment, and had to do rather with a question of parliamentary law than of medical etiquette. We might not be concerned to say anything about this latter topic, therefore, were it not that the *Times's* utterances represent a rather widely spread impression among people who do not know or do not think.

The customs which hedge about medical men in their dealings with each other, however, are not in any way mysterious or nonsensical. They are the natural outgrowth of a long experience among persons whose relations with each other and with society are peculiar. The family doctor who has watched for a generation over his patients, learned their illnesses, their weaknesses, and innermost domestic secrets, does not stand in the same relation to them as the business man. If the family at any time want other or additional medical advice, there exist technicalities which must be gone through with which simply provide justice to the regular physician and which in reality are a protection to the patient.

It has been found that on the whole the medical courtesies tend to lessen friction and prevent ill-feeling among professional men, while promoting also the welfare of the patient. No doubt as society changes there will come a need of some changes in medical etiquette, but there will always be the professional courtesies as long as the art of medicine continues a liberal one and does not sink to the level of trading on the misery and credulity of the race.

City Hospital in Malden.—The corner-stone of a new city hospital was laid in Malden, Mass., last week.

News of the Week.

The Microbic Origin of Rheumatism. — Professor Bouchard has, in effect, been engaged in investigations concerning the cause of so called rheumatic arthropathies, most of the cases examined entering into the category of subacute and chronic rheumatism. With M. Chartrin, the professor has sought either in the articulation, or in affected parts contiguous to it, any germs that could be held responsible for the morbid changes therein discovered. In six cases out of ten the staphylococcus albus existed alone; it was associated in one instance with the S. aureus; in another with a short bacillus. Once the S. aureus was isolated, together with a new bacillus; twice cultivation experiments failed. The majority of the cultivations (cultures) were conducted on agar-agar or gelatine, in contact with air; others under sterilized oil. The professor completed his paper by the exhibition of specimens of artificially created rheumatic arthropathies produced in the lower animals by the intravenous inoculation of the above micro-organisms. In a large proportion of these experiments the bacillus pyocyanicus was employed. In a few cases, however, the introduction of the toxines secreted by the bacilli sufficed to set up a commencement of the process in the joints characteristic of rheumatism. The experimental production of these lesions requires generally a survival of one or two months or longer. In one rabbit, however, they revealed themselves in eleven days. It is interesting to note that, even when the characteristic lesions are reproduced after a short interval, muscular atrophy is associated with them as in man. The frequency with which the staphylococcus albus is met with in these arthropathies leads to the belief that some connection hitherto unsuspected exists between them and this particular micro-organism.

Some New Heart and Nerve Tonics.—Dr. Brown-Séquard's famous elixir has been the subject of many pleasantries, but the employment as therapeutical agents of extracts of organs or animal tissues seems nevertheless to be gaining ground. In a case of heart failure M. Onimus, of Monaco, has had recourse to the subcutaneous injection of an extract of heart-muscle, and he claims that this novel medication determined the disappearance of the orthopnœa. The other symptoms—shortness of breath, debility—were diminished by similar injections of a glycerine extract of spinal cord. In a typical case of glosso-labio-laryngeal paralysis, which had reached the last stage, great benefit is said to have been derived from the use of these nerve-extracts, and similar results are said to have been noted in cases of transverse myelitis, chronic spinal meningitis, and early locomotor ataxia. MM. Boinet and Boy-Teissier have been recently studying the effects on the heart of an extract of cactus grandiflorus and of its alkaloid, cactine. Tried on frogs, guinea-pigs, and tortoises, the extract was found to increase notably the energy of the cardiac contractions, the effect being ephemeral, but readily reproduced by renewed doses. After the injection of eight or ten centigrammes the contractions were slowed and rendered arhythmic. The alkaloid cactine, injected in doses of from one to ten milligrammes, strengthened the contrac-

tions permanently, without exciting slowing or irregular action. A clinical trial has been made of a tincture of cactus, and the drug is found to act as a heart tonic in functional and organic diseases, without becoming accumulative in its effects. Large doses were given at frequent intervals (120 drops per diem).—*Lancet.*

A Recent Discussion on Goitre and Cretinism in Paris revealed the fact that there are now, in thirty departments of France, no less than four hundred and twenty thousand persons suffering under the former malady, while cretinism is becoming more common in the Pyrenean and Alpine valleys. It was proposed that the government should be asked to provide funds for the draining of the soil of the districts chiefly affected, and that steps should be taken to supply the inhabitants with filtered water. For the treatment of cretinism it was suggested that some of the old transport ships might be converted into naval hospitals.

The New York State Medical Association meets in this city, October 28th, 29th, and 30th, at Mott Memorial Hall. Among the papers to be read are "Preventive Medicine," by Dr. Henry C. Van Zandt; "The Theories of Rheumatism," by Dr. John Shrady; "Heredity and Environment," by Dr. Judson B. Andrews; "Biblical Medicine," by the Rev. Dr. William C. Bitting; and "Biology and Medicine," by Dr. Hubbard W. Mitchell.

The Congress of German Naturalists and Physicians held its sixty-fourth annual meeting at Halle, beginning September 21st. Professor His, of Leipsic, presided; addresses were delivered by Professors Nothnagel, Ebstein, and Ackermann. A disinfecting apparatus, invented by Dr. Hermann Rohrbeck, of Berlin, was exhibited in the garden of the medical clinic, and attracted much attention. Its purpose is to render the flesh of locally tuberculous animals and other objectionable meat fit for human food, by subjecting it in all its parts, and within a short time, to a temperature of at least 100° C. It differs from the usual disinfectors in two respects: it lets no "dry" steam in, and it leaves no remnants of air in the interior of the disinfected articles. The latter purpose is attained by condensing the steam with which the apparatus is filled, by washing over a double cover adjusted in the boiler, a process which can be repeated *ad libitum*. In the Section of Hygiene, Professor Lehmann, of Würzburg, made a highly important and astounding communication regarding the pollution of the meal of which the coarse rye-bread eaten on the Lower Rhine is baked. In the Section of Dentistry Professor Hollaender, of Halle, reported on a new anæsthetic called pental, which does not produce total unconsciousness, but only a kind of hypnosis. In the Section of Internal Medicine, Dr. P. Guttmann, of Berlin, reported on two typical cases of malaria which had been cured by the internal administration of methylene blue; and Dr. Aufrecht on one hundred and twelve cases of pulmonary tuberculosis treated by him with tuberculin in the Magdeburg Hospital. He stated that forty eight patients had recovered, while thirty-seven had considerably, and twenty-two perceptibly, improved, while in five cases the remedy did not take effect. Hectic cases were excluded. He began with one-twentieth of a milligramme, and gradually raised the dose to five milligrammes. He injected every other day, and stopped either temporarily or altogether the moment any disturbances of the process appeared. He thinks that the fluid confers immunity on the parts round the tuberculous foci, and thus prevents the spread of the disease. Other practitioners reported similar successes, and one of them related that Koch had said to him, "The number of such reports is increasing daily, and I am still firmly convinced that my discovery is a good one." The next year's Congress is to be at Nnremberg.

A Historical Case of Infection.—The late General Boulanger, who devoted the last year of his life chiefly to nursing his mistress, contracted phthisis from her and was suffering from it at the time he committed suicide.

Dr. James C. Wilson was elected by the Board of Trustees of Jefferson Medical College to the chair of Practice of Clinical Medicine, to succeed Dr. J. M. Da Costa, who resigned last spring.

The Human Heart at the World's Fair.—Dr. Nardyz, a Pittsburg physician, is at work upon an immense papier-maché model of the human heart, for exhibition at the World's Fair. It will be three feet in diameter.

Fowler's Solution for the Cure of Warts.—Dr. Müller, of Hamburg, recommends Fowler's solution for the removal of these unsightly objects. He states that he has had uniformly good results with it. His practice is to commence in adults with two drops thrice daily, with children half a drop for a dose. The dose is to be increased week by week. The cure generally follows in from two to three weeks, the warts disappearing gradually and almost imperceptibly.

Abuses in the Indiana State Insane Asylums.—Some two or three years ago the use of the Indiana State Insane Asylums as spoils resulted in the most abominable abuse of the helpless and miserable inmates. Now a similar cause, it appears, has produced a similar result in the boss-ridden State of Pennsylvania. The Committee on Lunacy of the State Board of Charity find that charges of mismanagement and cruelty in the State Insane Hospital are substantially true. Patients were assaulted by attendants, involving serious bodily harm, and although the facts were known to the first assistant physician and the superintendent, they failed to dismiss the offending attendants or to notify the Committee on Lunacy, so that legal steps might be taken. The committee had ocular proof of the fact that the system of keeping the hospital books was imperfect. For years past the dispensing and compounding of medicines for the patients, and the responsibility of the hospital pharmacy, had been in the hands of an employee not legally or actually qualified for such responsible work. It was only after repeated remonstrance from the committee that a competent pharmacist was employed. To quote from the report: "Every allowance having been made for possible exaggeration, the committee find, upon careful examination of the evidence, that the medical control of the hospital is lax and inefficient; that the regulations imposed by the lunacy law have been repeatedly violated and set at naught; that barbarous and cruel practices upon patients by attendants have gone unreported and

unpunished, and that inefficient care has been bestowed in the selection and training of attendants."—*Civil Service Reformer.*

Medical Attendance in the Jury-room.—The sanctity of a jury-room appears to be so well guarded that even in case of sudden sickness a physician may not enter except after due process of law. In the Foss will case, tried recently in Boston, the jury were deliberating, when, late in the evening, one of them was suddenly attacked with what proved to be a stroke of apoplexy. The officer in charge notified the deputy-sheriff; who, not having authority to let anyone into the jury-room, drove across the city and informed the sheriff; but even this official was not high enough to act, and another expedition started in search of the judge. As the latter happened to be at home, the requisite order was obtained to summon a doctor.—*Boston Medical and Surgical Journal.*

The Late Dr. Parkes.—At the opening of the session of the Rush Medical College, in Chicago, on September 29th, a bronze bust of the late Dr. C. T. Parkes was unveiled with appropriate ceremonies.

The Postal Service and the Quacks.—We have received copies of circulars, presumably sent to all the postmasters of this country, in which extraordinary inducements are offered them in order to secure, by their aid, lists of persons that receive their mail at a specified office. The lists are to be of two kinds: all those not invalids, and those that are suffering from any chronic ailment. The postmaster is especially instructed to give "the names of persons suffering from rupture (breach), for which we possess a new and radical means of cure; also, those suffering from piles, or from fistula in ano, for both of which diseases we have new, improved, and radical methods of treatment; or of those afflicted with diseases of the throat and chest; or of the digestive organs, heart diseases, diseases peculiar to women, scrofulous diseases, as fever sores, white swellings, and old sores or ulcers; also, the names of any sufferers from diseases of the urinary organs, as diabetes, Bright's disease, gravel, inflammation of the bladder, stone in the bladder, strictures, and kindred affections; or from epilepsy or fits, chorea or St. Vitus's dance, paralysis, curvature of the spine, nervous debility; or from tumors, or any other chronic diseases; for all of which our institution offers special advantages and facilities for treatment. Please to be particular to indicate opposite every name, 'in the Invalids' division of the list,' the disease (if known to you) with which the party [*sic!*] is supposed to be afflicted." Upon the receipt of the list the presumption is that the people will be deluged with testimonials and promises to cure.—*Medical News.*

Physicians Boycotted by Debtors.—We learn that the thriving town of Stuttgart, Ark., is in the throes of a genuine sensation, caused by the action of the leading physicians of the place forming a combine against citizens who do not settle their doctor's bills promptly. Several days ago the medical men of that place formed an organization for their protection. They have a clause in their by-laws prohibiting any member from responding to a call sent in by a citizen whose name appears on the bad-pay list. Consequently a mass meeting, attended by three hundred citizens of Chester County, was held, and strong denunciatory resolutions were adopted against the physicians belonging to the organization. It was unanimously agreed that a general boycott should be inaugurated against all the physicians unless they leave the society in ten days. It is quite probable that the assemblage was composed of men guilty of not paying their doctors, as otherwise there would have been no cause for action. With the doctors it would seem to be the question whether it is best to work for nothing or not work at all. Except for the work, the net result would be the same. The only compromise for such of them as must work is to club together and found a free dispensary, New York style, and establish a teaching centre. There is nothing like seizing upon the next best thing.

Tuberculin Again to the Front.—Professor Koch has published an exhaustive article describing the preparation of tuberculin. He declares that he has at last succeeded in purifying the lymph of all inflammatory tendency, but the reactions remain. In other words, tuberculin is said to be improved as tuberculin, but practically the tubercle bacillus is as rampant and defiant as ever. A year ago this would have been surprising news, but since that time lymph, having gone up like a rocket, comes down as a stick upon which we must fly a half-masted flag. Alas! it has not lived long enough for a first anniversary.

The Death of Dr. Christopher Johnson.—Dr. Christopher Johnson, one of the most eminent of Southern physicians, died suddenly in Baltimore, October 11th, in the sixty-ninth year of his age. The end was not expected, as he was, apparently, in the full possession of his strength and faculties, and had not given up his practice. Dr. Johnson was graduated in medicine in 1843. He succeeded Dr. Alan Smith in the Chair of Surgery in the University of Maryland, and contributed greatly to the building up of that institution. He devoted a great deal of his attention to pathology, and his contributions to medical journals made his name widely known. He introduced many improvements in instruments. He travelled extensively, and was a leading figure in the cultured society of Baltimore.

The Southern Surgical and Gynecological Association.—The fourth annual session of the Southern Surgical and Gynecological Association will be held in the hall of the House of Delegates, in the city of Richmond, Va., on Tuesday, Wednesday, and Thursday, November 10, 11, and 12, 1891, under the presidency of Dr. L. S. McMurtry, of Louisville. The Secretary, Dr. W. F. B. Davis, of Birmingham, Ala., is arranging a full and interesting programme; and the Chairman of the Committee of Arrangements, Dr. Hunter McGuire, of Richmond, announces that the facilities for a successful meeting are complete. This Association is essentially a working organization, and is doing a great work in the Southern States. The three volumes of "Transactions" already issued are highly creditable to any society or country, and have elicited the highest commendation from the medical press in this country and Europe. The meeting in Richmond promises to be the most successful the Association has held. Members of the profession generally are cordially invited to attend.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, October 12, 1891.

ROBERT ABBE, M.D., CHAIRMAN PRO TEM.

Talipes Equino-varus; Phelps's Operation.—DR. WILLY MEYER presented a young man, aged seventeen, who had entered the German Hospital, on account of congenital talipes equino-varus, last October. He had never received treatment from a physician. Having heard of the favorable results from open incision practised by Dr. A. M. Phelps, he concluded to do this operation. After making the cutting operation the foot was easily placed in the over-corrected position, in which it was retained by plaster-of-Paris dressing. The first splint was allowed to remain six weeks, at the end of which time the wound had almost entirely healed. The patient was able to walk about after the second splint was applied. The operation was performed in October, and the patient was discharged in February. He was at present able to walk on the full sole of the foot. There was slight motion in the astragalo-tibial joint.

Gastrostomy for Cancerous Stricture of the Œsophagus.—DR. MEYER also presented a man, seventy-one years of age, who had entered the German Hospital on April 5th of the present year, on account of cancerous stricture of the œsophagus. He had been steadily failing in health, had lost much in weight, was only able to swallow fluids, and therefore it was decided to perform gastrostomy at once. Von Hacker's procedure was adopted of separating the belly of the left rectus muscle, in order that it might act as a sort of sphincter and prevent leakage around the stomach-tube. The incision was made a little below the ribs on the left side, about three quarters of an inch from the median white line. After the abdominal cavity had been opened the stomach was stitched on its anterior aspect at a spot which could be easily brought forward. He waited forty-eight hours before giving food through the inserted tube. The opening into the stomach was not made with the Paquelin cautery, but with the knife, which enabled one to make the incision just the size he wished, or just large enough to admit the drainage-tube. The patient had gained in weight since the operation.

Result after Open Operation for Club-foot.—DR. A. M. PHELPS presented a girl, aged four years and a half, who was born with talipes equino varus in the left foot. She had undergone treatment at different hands before she reached him, which was last July. He cut the tendo Achillis, and on the inside and sole of the foot the tendons of the contracted muscles, dressed the wound in the over-corrected position, and, after two months, performed osteotomy upon the femur, just above the knee, to further place the foot in the straight position. The result had been very satisfactory. There was some motion in the toes. It had been objected that if all the tendons were cut there would be loss of motion in the toes, but this case and other experience of the speaker had shown that they usually regained their mobility, at least in some degree. Even when entirely lost, the patient could walk about as well as if there were mobility. It had been further objected that the open incision would leave a tender scar, but he had had no such result in about one hundred and eighty cases which he had operated upon.

Dr. Phelps showed photographs of a number of cases as they appeared before and after operations, and justified the treatment which he adopted. Believing that the equinus preceded the varus, he cut the tendo Achillis first, then divided the soft parts on the inside of the foot in the order in which they were put upon tension, while trying to straighten the foot, going as far as might be necessary in order to over-correct the malposition. If division of the tendons was not sufficient, he went on to do osteotomy, but in 160 cases he had to resort to osteotomy in only 17. The astragalus was first attacked, then, if necessary, the os calcis, etc., and finally, if called for, do Pirogoff's amputation. To recapitulate, first try strong manipulation and fixation; second, subcutaneous tenotomy; third, open incision; fourth, linear osteotomy on the astragalus; fifth, attack the cuneiform and os calcis; sixth, take out the cuboid and scaphoid; seventh, amputate. But suppose one first performed the severer osteotomy, and failed to correct the deformity, what could he do next? By proceeding with the milder operations first, one would find that he could avoid osteotomy in more than seventy-five per cent. of the cases. It was not right, in his opinion, to begin with osteotomy, if for no other reason than that about five per cent. of the cases proved fatal. Removal of the astragalus had been largely abandoned by European surgeons.

DR. V. P. GIBNEY said he thought Dr. Phelps's operation was a good one, but he regretted to hear removal of the astragalus spoken of so discouragingly. He believed that with the same amount of after-care given the foot by way of dressings as Dr. Phelps gave his cases, equally good results would follow removal of the astragalus. He thought removal of this bone was easier than division of the astragalus and forcing it around into position, as practised by Dr. Phelps. He was, in fact, better pleased with removal of the astragalus than with other operations on the bones. He had tried Dr. Phelps's method in only two cases, one of which was a failure.

DR. REGINALD H. SAYRE was in accord with the remarks of Dr. Phelps, except that he preferred to divide the soft tissues in the sole of the foot before instead of after cutting the tendo Achillis. He thought he had better control of the foot while wrenching it around than after cutting the tendo Achillis. He emphasized what Dr. Gibney had said regarding the necessity for keeping the foot in the new position long enough. Until the child was enabled by voluntary muscular action to bring the foot into correct position the case was not cured.

DR. MEYER thought there were few patients under four years of age in whom the deformity could not be cured by manual force, and where this could be done it was certainly better than to operate.

DR. KETCH and DR. ABBE made some remarks, the latter expressing surprise that so much toe motion had been retained in these cases, for it seemed hardly probable that in the open wound tendon united to tendon in the relations existing before the operation.

DR. PHELPS said that Schede had found the tendons united in the order in which they had been cut in one case in which he had opportunity to make a dissection, death having taken place from pneumonia.

Dermatol, a Substitute for Iodoform.—DR. C. A. POWERS presented a box of dermatol, with the use of which he had become acquainted while in Europe. Its advantages over iodoform were that it was absolutely non-poisonous and non-irritating. During the last two months he had employed it in somewhat over one hundred and fifty cases. It caused wounds and ulcers to heal in an extraordinarily short time, being in this respect far better than iodoform.

THE CHAIRMAN had had some experience with the remedy, and regarded it as the most drying and purifying of all the powders when applied to weeping ulcers, etc.

Laparotomy for Acute Intussusception.—DR. B. F. CURTIS read the paper, drawing some practical lessons from a case whose history was given. The man was taken to the hospital, after he had remained in charge of a physician for three days, with symptoms which pointed to some grave intestinal trouble, although it could not be asserted before the operation whether it was a case of acute perforating peritonitis or intussusception. Some of the symptoms pointed to the one condition, some to the other. There was pain over the abdomen in general, there was vomiting which assumed a fecal odor, there

were no passages, no tenesmus, no distention. The man had phthisical changes in the lungs, and it was thought probable there were tubercular changes in the intestines. Dr. Curtis opened the abdomen; straw-colored serum escaped; the intestine was examined, and at first the intussusception was passed over under the supposition that it was fecal matter, but going over it the second time its true nature was recognized. At least eight inches of the ilium were involved. Four inches were in poor condition, and were placed at the abdominal opening, surrounded by gauze, the idea being that in case it should rupture the intestinal contents would find their way out instead of into the abdominal cavity; if it did not rupture, the gauze could afterward be removed and the wound closed by suture. The operation lasted forty-five minutes. The patient died within five hours, but before death there was a passage, which proved that the gauze about the loop had not caused obstruction by pressure or traction. The case showed that the adhesions and pathological changes might be very slight, although the intussusception had lasted several days. It further illustrated the need of early operation, for it was not unlikely the patient would have lived had relief been brought even twenty-four hours earlier. Another case was cited which went to show that a critical collapse might occur so quickly that even in a short interval the patient might fall from a favorable to a hopeless condition. The dilatory course pursued by both surgeon and general practitioner, but especially by the latter, often proved fatal to the patient.

Would Make an Artificial Anus.—The Chairman related a case of intussusception in the small intestine, operated upon by him last summer; in this instance also there being absence of diarrhœa, mucous or bloody stools. The patient died on the table. Regarding the statistics referred to in the paper, there being fourteen cases in which suturing was done after resection of the gangrenous intestines, with three recoveries, and fourteen other cases in which an artificial anus was made, with only one recovery, such statistics were not of much value as deciding the comparative safety of the two procedures. Evidently, in the majority of instances where an artificial anus was made, this course was pursued simply because the case was too desperate to justify immediate resection. His own feeling was decidedly in favor of making an artificial anus in all the cases of obstruction with gangrene, extensive perforations, etc., and subsequently any suturing could be done which might be necessary.

A Critical Study of the Biceps Muscle as Related to Disease In and Around the Knee-joint.—Dr. E. M. Mosher read a paper with this title. She had been led to make a critical study of the biceps as related to diseases in and around the knee-joint, by having to treat a case which she related somewhat in tragical detail.

The patient began to suffer after sitting two hours with the knee bent, being unable during that time to change her position. Subsequently she had pain in the joint if she stood long at a time, and when the knee was in any way exposed to strain or slight injury. In fact, during seven years the longest time she was off crutches was a year and a half. She was subjected to various kinds of treatment at the hands of various surgeons. Some diagnosticated periostitis, some synovitis, some a strained biceps, etc. On carefully studying this case, Dr. Mosher came to the conclusion that the action of the biceps muscle was not only the source of irritation which perpetuated the trouble, but that it was also the original cause of it. After consultation with Dr. Rushmore the tibial tendon of the biceps was divided, after which the patient was practically relieved. Considerable atrophy took place in the lower half of the short head of the biceps, and external rotation was impaired. The author claimed to have demonstrated by anatomical dissections that the biceps, and the biceps only, had through its tendon intimate connection with the interior of the knee-joint. Fibres of the biceps coming from the supra-condyloid ridge were inserted into the coronary ligament, through it were connected with the capsular ligament, and thus with the intra-articular cartilage, synovial membrane, and very interior of the joint. In the case whose history she had given there had been, and she believed the same occurred in other cases, forced action of this portion of the biceps, and injury had taken place within the joint, which must necessarily be kept up as long as the limb was in use.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 13, 1891.

H. M. Biggs, M.D., President, in the Chair.

Aneurism of the Basilar Artery.—Dr. W. L. Carr presented a specimen of aneurism of the basilar artery, just at its junction with the vertebral. The specimen was removed from a young man, twenty-eight years of age, a telegraph lineman by occupation. Eight years before he presented himself for the present trouble; he fell thirty feet, and struck on the buttocks. This fall apparently gave rise to no serious consequences. There were no signs of syphilis, and the patient gave no history of such infection. With the exception of a severe attack of malaria while in Georgia, his health remained good up to April 11th, when Dr. Hoyt, of this city, to whom the speaker was indebted for the observations on the case, was called in to see the patient. He had been seized with clonic convulsions in which the head was thrown back. He complained of pain in the back of the head, and in the frontal, dorsal, and lumbar regions. There was slight tremulousness of the tongue when protruded, slight photophobia, and symmetrical sluggishness of the pupils, with possibly a slight drawing of the face to the left side. There was also a scarcely perceptible ptosis on the right side. The reflexes were lost and sensation was diminished over the extremities. Urination and defecation were normal. Two days later, when first seen by the speaker, the grasp on the right side was somewhat diminished; his pulse was 54 and full, respirations, 19; pupils somewhat contracted and sluggish; speech very deliberate, but he answered questions correctly, and related events in their chronological order. The pain in the cervical region was the most prominent symptom. One week later, another convulsion occurred, and he died very soon afterward.

The post-mortem examination was made twenty-four hours after death. He was indebted to Dr. W. H. Porter for assistance in this examination, and in the preparation of the report of the autopsy. The cranium was found to be unusually thick, and on the outer surface, on the anterior portion of the calvarium, on the left side, was a deep pit as if there had been a fracture of the skull, but the internal table was intact. The dura mater was fully three times the normal thickness, and was adherent to the pia mater along the whole line of the great longitudinal fissure at the vertex, and could not be separated from the underlying tissues, except at the expense of the pia mater and the cortical substance of the brain. When the calvarium and dura mater were removed there was practically no escape of blood or serum. At the junction of the medulla and pons, all over the anterior surface of the pons, and in the inter-pedunculated space, at the base of the fissure of Sylvius, there was a distinct hemorrhage and clotting, which was most marked over the pons and the Sylvian fissure. The hemorrhage was confined between the pia mater and the brain, probably on account of the great thickening of the pia mater. The lateral ventricles were distended with bloody serum, and on the right side there was a little clotted blood, There was no laceration of brain-tissue. The hemorrhage was certainly not intra-cerebral, as on dissecting along the Sylvian fissure the vessels were found to be natural. Springing from the posterior surface and right side of the basilar artery was a sacculated aneurism, three-eighths of an inch in diameter, which had burst,

giving rise to the hemorrhage, cerebral compression, and death of the patient.

Dr. Carr said that he had only been able to find the record of one other such case among the "Transactions" of the Society, and that one was presented by the President in 1889.

Dr. W. H. Porter said that although there was no syphilitic history, it was difficult to understand how, in so young a man, there could be such an extensive thickening of the meninges, except as the result of syphilis. This disease might easily bring about such changes in the cerebral vessels that they would be unable to regulate the nutritive supply, and so would cause an unusual thickening and a strain upon the vessels. It might perhaps also explain the development of the aneurism. Again, it was interesting to note that the transverse foramen and the foramen of Magendie seemed to be completely occluded, and the left ventricles were very much dilated—which, together with the thickening of the pia mater and compression of the cortical substance, would explain in a measure the sluggishness of intellect and the primary convulsion which occurred before the hemorrhage. This was the fifth case of cerebral aneurism which he had seen, including in this number aneurisms affecting the middle, posterior cerebral, and basilar arteries.

Dr. B. Sachs thought there was no other probable explanation of the condition presented, except specific infection, and this view was favored by the existence of the aneurism; for it was generally conceded that aneurisms were most commonly of syphilitic origin.

In answer to a question from Dr. Mary Putnam-Jacobi, as to whether he considered a syphilitic endarteritis to be the cause of the aneurism, Dr. Sachs said, that although this form of endarteritis frequently tended to obliteration, examinations had shown in some of these cases a syphilitic endarteritis of other vessels. Aneurisms did, of course, occur in young persons where there was no suspicion of syphilis; thus Osler reports a very interesting case of aneurism of the anterior cerebral artery occurring in a boy of six years, where there was a history of traumatism, and a distinctly negative history as regards syphilis.

The President thought the case presented was extremely rare. As bearing upon this question of the etiology of such aneurisms, he desired to refer to a case in which there was an aneurism at the junction of the anterior communicating artery, which ruptured and caused sudden death. The case occurred in private practice, and the patient, who was twenty-seven years of age, and a prominent young man in this city, gave a very accurate history. There was absolutely no specific history obtainable, and there was no reason to suspect such infection. There were no changes in the blood-vessels of any part of the body which were suggestive of syphilis or any other disease. At the site of the aneurismal dilatation and rupture, nothing could be found except a thinning of the coats, and hence it seemed probable that the condition was the result of a congenital deficiency in the arterial walls, rather than the result of disease.

Colloid Secondary to Internal Cancer.—Dr. W. H. Porter presented a small tumor which had existed in the temporal region as a small papillary protrusion. The case had been sent to him by Dr. Janvrin, and gave a peculiar clinical history. A little over one year ago the patient, a gentleman apparently in robust health, had an extensive growth removed from the rectum, and an examination of the portion removed showed it to be carcinomatous. The patient made a slow but complete recovery. About three months later he received a blow upon the temple, and soon afterward the present tumor developed and became so soft and fluctuating that it was supposed to be an abscess, but an incision did not evacuate any pus. After about three months more this tumor was removed and sent to the speaker for examination. He found that instead of presenting the characteristic appearances of a true epithelioma, it had the structure of a colloid. An examination of the rectum at this time showed a recurrence of the disease.

It seemed to him very strange that an integumental growth should follow one which apparently originated in the alimentary tract, and that this secondary growth should be of a colloid nature rather than of the epithelial type commonly found in the skin. He had never seen such a growth in the integument, and in a casual examination of the literature of the subject he had not found any such case reported.

A Renal Calculus.—Dr. J. E. Weeks, on behalf of Dr. E. D. Fisher, presented a specimen of renal calculus which occupied the whole of the kidney, the cortex of which was greatly atrophied. The other kidney was normal. The specimen had been removed from a laborer of middle age, who had not presented any symptoms referable either to the kidney or to the bladder. The nature of the calculus had not yet been determined, but it was extremely hard.

Dr. Mary Putnam-Jacobi said that in connection with such extensive disease of one kidney it might be interesting to call attention to a method recently published by Dr. Willy Meyer, of determining by means of the cystoscope whether or not both kidneys are functionating. In the case reported, which was that of a woman, he had found that, by counting the number of drops of urine discharged from each ureter in a given time, one could form a very good idea of the functional activity of each kidney. In this particular case, fifteen times as much urine was discharged from one ureter than from the other, and at a subsequent operation it was found that the kidney which had excreted the urine so slowly was extensively diseased.

Dr. Porter said that apparently there was no kidney structure remaining in the specimen just presented. The method of diagnosis just alluded to he considered a very important one. He cited the case of a female whose symptoms had all been referable to the bladder, with the exception of one very slight attack of renal colic. The bladder symptoms were so severe that an opening was made into this viscus from the vagina. The urine discharged from this opening was highly acid, and contained leucocytes and a small quantity of mucus and albumin. Subsequently the ureters were catheterized and the urine from each kidney separately subjected to examination. The urine from one kidney was perfectly normal, while that from the other was highly acid and contained mucus, corpuscles, and albumin. Several surgeons having failed to detect any stone, an exploratory operation was performed, and a large stone was found in one kidney. It was broken up and removed, and the patient recovered. His experience had led him to conclude that in cases where there were bladder symptoms associated with highly acid urine, the trouble was higher up than the bladder. In every case he had seen, where an opportunity had been afforded to confirm the diagnosis by operation or autopsy, this statement had held good.

The President said that he had been much impressed with the comparative frequency, in the autopsies at the Almshouse, of these cases of renal calculi occurring in patients who had given no history of such a condition. He had thought it likely that in the early development of the stone there had been symptoms produced, and that later on the mucous membrane became tolerant of its presence and gave rise to no further symptoms. It is not at all uncommon to find one or more calculi of moderate size in the pelvis of the kidney when there has been nothing to suggest renal disease.

Dr. J. E. Weeks presented the brain from a man, sixty five years of age, who died in the Almshouse on April 26th, from congestion of the lungs following "the grip." Ten years ago he had an attack of right hemiplegia, from which he recovered, and a few years later he had another attack, from which he almost entirely recovered. One year ago he had still another one, which was accompanied

by some defect of vision, and some difficulty in speech, and in the recognition of objects. Examination showed that he had left-side hemianopsia; the interior of the eyes and the movements of the eyes were perfectly normal, the pupils reacted perfectly to light when the light was on either the blind or the seeing side, and the division between these parts was perpendicular and almost perfectly straight. At first there was no motor aphasia, but during the last few days of life there was amnesic aphasia and agraphia.

On post-mortem examination the viscera were found to be in fair condition, with the exception of the kidneys, which were small and granular. The right side of the brain was normal in size; the left side of the cranial cavity was partly occupied by brain-substance, and partly by a cyst, the outer wall of which was made up almost entirely of pia mater, while the inner wall was formed by the brain. The cyst-wall was so very thin that although the brain was carefully removed the cyst collapsed and its serous contents escaped. The basilar artery was found to be atheromatous in various places, and at the point where the posterior cerebral artery is given off there was a fusiform aneurism containing a clot, which was apparently of post-mortem origin. The specimen showed the left posterior cerebral artery reduced to a cord, and the right of normal size. The left middle cerebral had also been converted into a cord, and at one point, where a small branch was given off, there was considerable thickening. The ascending parietal and ascending frontal convolutions, and the motor region, were almost intact. In the vicinity of the island of Reil the brain-tissue was greatly atrophied, as was also the lower frontal convolution. The occipital lobe had almost disappeared, and nearly all the brain-tissue back of the Sylvian fissure was shrunken. There was a little pigmentation and a very small spot of softening in the occipital lobe.

The symptoms were those only which could be readily accounted for by the loss of brain-substance. He was unable to say what was the cause of the arterial changes, as there was no history of syphilis. The patient was a fairly intelligent man, and the convolutions, though extremely small, were all present. The preservation of a portion of the superior temporal convolution accounts for the absence of mind blindness. The space which had been apparently previously occupied by the temporal lobe was filled by the sub-pial cyst, but this cyst did not involve the brain.

Dr. Mary Putnam-Jacobi said that it had often been noticed that the inability to recall the names of objects was often present, when the recognition of objects and the capacity for other work still persisted, and this had been explained by supposing that, so long as the mind had a visual image to work with, it was less in need of a sign than in the case of other parts of speech which could not be replaced by a visual image. The case under discussion was quite in accordance with this line of reasoning.

Dr. Sachs said that it was very unusual to find such extensive atrophy in the adult brain, and that no matter how long a thrombosis may have existed, he thought it hardly likely that it would result in an entire absence of the occipital lobe. It seemed to him more probable that it was a case of congenital deficiency of the brain. Although it was the rule for such cases to show defective intellect, it was to be remembered that quite a large percentage of cases of typical congenital deficiency of the brain had been found accidentally in persons apparently normal, who had died of some other disease, and this was readily explained by supposing that one hemisphere took upon itself the functions of the other.

Dr. Porter concurred in this view of the etiology of the condition found in the case under discussion.

The President said that he had seen a great many cases at the Almshouse where there had been large areas of destruction of brain-tissue from softening, thrombosis, hemorrhage, and similar causes, but he had never seen a case in which the convolutions had been so well preserved as in this specimen, and yet where the degree of atrophy was so extreme.

Dr. W. P. Northrup thought the history of the case seemed to indicate that there had been an œdema of the pia and subsequent softening, and he thought the explanation given by Dr. Weeks was the correct one.

Dr. Weeks replied that the history was entirely against its being a congenital defect. The total loss or atrophy of the occipital lobe could be accounted for by the total occlusion of the posterior cerebral artery, which furnished the nutrition to this lobe. The case was very similar to one which he had under observation for two years or more, and who was still living. The patient is a woman, who in June, 1887, one week after confinement, suddenly developed left hemianopsia, and for a short time, left hemiplegia. She recovered from the latter, but the former is still present. She undoubtedly had an embolism of the right middle cerebral artery. Fourteen months later, she was again confined, and about one week after this she developed a right-side hemiplegia with total mind blindness. At present she has amnesic aphasia and agraphia.

The specimen presented by Dr. Weeks was referred to a committee consisting of Drs. Weeks, Sachs, and Van Gieson, for further investigation and report.

Dr. Sachs presented the brain from a case of acquired cerebral palsy, occurring in a child who was eight and a half years of age at the time of his death. Typical right hemiplegia was developed without coma or convulsions, and it pursued the ordinary course for a long time, when the child suddenly fell down without coma or convulsions. The old hemiplegia was increased, and the child passed into a comatose condition; there was double optic neuritis, the other side became involved, as also some of the cranial nerves, and after several weeks the child died in coma. A diagnosis was made of initial palsy, due to old meningeal hemorrhage, which had probably ended in a cystic condition, and that this cystic tumor was the cause of the deepening of the old hemiparesis. The autopsy substantiated this diagnosis.

The cystic condition of the cortex and the enormous size of the tumor were especially noteworthy. The basilar symptoms developed in the case were supposed to be due to basilar meningitis, and the only way of associating these two sets of facts was by supposing that the original tumor was a tubercle. The basilar symptoms were produced by the second tumor in the temporo-sphenoidal lobe. It has been supposed that accidents to the cerebral vessels in children were comparatively rare, and quite recently a writer made the statement that these accidents were necessarily the result of embolism. The structure of the cerebral vessels in children has not been sufficiently studied, but, as the speaker had pointed out, fatty degeneration of the blood-vessels in the young was extremely frequent, and therefore it was reasonable to suppose that it might play the *rôle* that atheromatous degeneration does in adults. The axis of the brain had become much distorted by the tumor, and the first symptoms were observed about eight weeks before death. The tumor extended from the frontal region to the occipital. The structure of the tumors seemed to him to be that of mixed sarcoma, but as some of his specimens bore a strong resemblance to tubercle he would like the opinion of the Society upon this point.

Dr. J. M. Byron said that he had never seen a giant-cell sarcoma in which the nuclei were so distinct, and, in fact, there were only two pathological conditions in which the nuclei showed so clearly as in the specimen presented, *i.e.*, in tuberculosis and in actinomycosis. The specimen showed cells which were perfectly characteristic of tubercle, and hence he looked upon this specimen as one of large solitary tubercle.

Dr. Northrup said that he was of the same opinion, for, in addition to the giant-cells present, there was a well-defined area of coagulation necrosis.

Dr. Sachs remarked that in the first specimen which he had examined there were no giant-cells at all.

The specimen was referred to the microscopical committee for examination.

Syphilis of the Brain.—Dr. Sachs also presented microscopical specimens from a case of syphilis of the brain, and also other slides showing the difference between a gumma in the pons, and a gummatous infiltration.

The patient, a woman, thirty-five years of age, had had repeated attacks of paralysis, from which she had recovered. Finally, she had an attack of paraplegia with involvement of various cranial nerves, and the diagnosis became easy of syphilitic deposit in the pons. The interesting feature was that there was not only a syphilitic infiltration of the pons, but a general infiltration along the course of the entire cord, and along the brain axis. He preferred to call this condition multiple cerebro-spinal syphilis, as the symptoms resembled very closely those of multiple cerebro-spinal sclerosis.

Dr. Northrup presented a slide from a case of gonorrhœa, showing the characteristic grouping of the gonococci about the nucleus and within the cell-body. The specimen had been obtained from a healthy young adult on the third day after exposure, and the first day on which there were any unusual symptoms about the urethra. It was his first attack, and the disease ran a typical course, and now, three and one-half months later, there is still a persistent gleety discharge, in which are a few gonococci.

Children among the poorer classes not infrequently have a suspicious vaginal discharge, and it is sometimes desirable to determine whether this is simple or specific in its nature. He thought the presence of the gonococci in these characteristic groups was considered now to be an exact test in medico-legal cases.

A Method of Rendering Thick Sections of Tissues Transparent.—Dr. J. West Roosevelt said that while investigating the structure of the lungs, the idea had occurred to him that it might be possible to saturate the lung with some substance which would render even large and very thick sections quite transparent. He had found a mixture of oil of cloves, oil of cedar, with sometimes a small proportion of Venice turpentine, could be made with such an index of refraction as to bring about such a novel and desirable result. The proportions of the different ingredients necessarily varies a good deal with the different specimens of the oils, but by beginning with two thirds oil of cedar and one-third oil of cloves, and stirring with a flint glass rod, the correct index of refraction could be readily determined, for when the proper proportions were obtained, the rod would be nearly invisible in the mixture. Afterward the lungs were bleached in this mixture until the desired degree of transparency was obtained.

This method had incidentally shown a very interesting and an exceedingly satisfactory method of demonstrating the intricate structure of the air-vesicles.

Dr. Roosevelt exhibited some specimens which had been so prepared, and remarked that he thought the method was opportune, as it would probably prove useful in studying the circulatory conditions existing in the brain.

The Society then went into executive session.

Lelior claims excellent results in the abortive treatment of herpes from the local use of 1 part of resorcin or menthol to 50 of alcohol. If there is much pain he uses gauze steeped in the following solution and covered with an impermeable dressing: Alcohol, 100 parts; cocaine hydrochlorate, 1 part; extract of cannabis indica, 10 parts; mint essence, 10 parts.—*Times and Register.*

To Prevent Sore Nipples.—Apply a mixture of tannin and glycerine, two drachms to the ounce, daily, during the last month of pregnancy. This renders the nipples tough, but elastic.—*Annals Hygiene.*

Correspondence.

EHRLICH'S TEST IN TYPHOID FEVER.

To the Editor of the Medical Record.

Sir: Have we in fact, in "Ehrlich's Test in Typhoid Fever," a really efficient, reliable, convenient, ready, and practical aid in the early diagnosis of typhoid fever, at a period, indeed, prior to the appearance of the rash or other recognized diagnostic symptoms, *i.e.*, as early as the fifth to the ninth day of the disease? Such, at least, is the claim made for the test, and it appears well founded.

In the article printed on p. 388 of the Medical Record of September 26, 1891, entitled "Ehrlich's Test in Typhoid Fever," and credited to the *Therapeutic Gazette*, the claim is virtually conceded and a brief synopsis of the test is given. It is to be regretted, however, that inaccuracy as to certain details mars that article which it would be unwise to excuse, because just a shade of suspicion of gross carelessness rests on its writer.

In describing test solution No. 2, he writes: "2. A five per cent. solution of sodium nitrate," etc., two errors in one line; for, as printed in the *Therapeutic Gazette* of February, 1891, test solution No. 2 is thus described: "A one-half per cent. solution of sodium nitrite," etc.

Ehrlich's test requires for its successful application the two following named test solutions: No. 1, containing a saturated solution of sulphanilic acid in diluted hydrochloric acid, reduced to five per cent., and No. 2, consisting of a one-half per cent. solution of sodium nitrite, to be kept in separate bottles until wanted for use; then forty c.c. of solution No. 1 and one c.c. of solution No. 2 are mixed together in a measuring-glass and briskly agitated, when the following named reactions take place, viz.: the hydrochloric acid and sodium nitrite react on each other, liberating free nitrous acid in the nascent state, which reacts with the sulphanilic acid and liberates in the mixture diazo-benzene-sulphonic acid, the essential substance in the final test mixture which is employed to react on the urine, to bring out the play of colors characterizing Ehrlich's test. While sulphanilic acid may be replaced by other similar bodies in preparing test solution No. 1, neither of the other compounds can be omitted in preparing the test solutions without spoiling and defeating the experiments; and yet the Record article not only substitutes sodium nitrate for sodium nitrite, as above shown, but also omits the sodium nitrite solution altogether in describing the "best method of performing the test," etc. But feel not abashed at this default, for the same omission occurs twice in the original and obscurely written article in the *Gazette*.

Speaking of the obvious importance of observing to the letter Ehrlich's directions and precautions for applying his test with success, that original *Gazette* article ascribes to Ehrlich the saying that "there are but few tests in chemistry which cannot be spoiled by careless manipulation," and verifies the remark in a truly singular manner.

And, now, as the final success or failure of Ehrlich's test depends on the intelligence and fidelity with which it shall be applied, ought we not, in justice to Ehrlich and all the interests involved, work as if we believed that whatever is worth doing at all is worth doing well? If Ehrlich's test have the practical utility that is claimed for it, then has the practice of medicine taken another step in advance which the profession, ever mindful of its responsibilities and duties, will gladly maintain.

George D. Wilber, M.D.

Pueblo, Col., October 10, 1891.

THE GEORGIA LIQUOR STATUTE.

To the Editor of the Medical Record.

Sir: In the Medical Record of October 10, 1891, p. 455, in commenting on the Georgia statute disqualifying any physician from practising medicine who is a drunkard, you close with the following remarkable sentence:

"If such a statute really exists, the physicians of Georgia should see to it that it is repealed, or be convicted of possessing neither manhood nor self respect."

The responsibilities resting upon the physician are so great that he, of all men, should have a clear head and steady hand, which faculties a man that drinks, and especially the drunkard, cannot have. The most of our railroads are discharging trainmen for getting drunk, or even drinking or loafing around saloons, and the public are sustaining the companies; and it seems only right that the State should protect its citizens against the physicians, railroad men, or any other class of men in whose hands the lives of the people are entrusted.

If physicians possess no manhood or self-respect, who will sit idly by and permit such a law to be enacted, or favor a law prohibiting a physician from practising, a railroad conductor or engineer from running an express train upon which I am travelling, who drinks or gets drunk, then I wish we could have more men who have no manhood and self respect.

Drunkenness is getting to be so frequent an excuse for crime, so frequent an excuse for irresponsible conduct of all classes of men, that it seems only just and right that the people should demand that everyone who holds the lives and health of people in his hands should have a steady hand, and a clear head to guide that hand.

It seems to some of your readers very remarkable, to say the least, that the editor of one of the best medical journals in the United States should make such a statement as the above quotation. It is all the more remarkable, when we consider that you, as an educated medical man, knowing the evil effects of alcoholics upon the human system, and the irresponsibleness of those who drink, especially to excess, in the face of all this to make the assertion, that he was devoid of manhood who would endeavor to stamp out drunkenness, or would forbid, by legal enactments, the drunkard from tampering with the lives of the people.

The physicians should take the lead in this matter of temperance, should instruct the people, educate them on the proper use and the fearful effects of the abuse of alcohol; and to a large class of your readers it seems only just and right, for humanity's sake, that every man who gets drunk, or runs to saloons, should not be permitted to hold any position where the health and lives of the people are immediately under his care or supervision.

Very respectfully, J. Z. POWELL, M.D.

LOGANSPORT, IND.

[Our esteemed correspondent is perfectly right in saying that no physician should ever get drunk, and that the community has a right to protect itself against any of the evils growing out of drunkenness. In all this we entirely agree with him, we only deplore the necessity of any such law as applying to Georgia physicians. Notwithstanding our great respect for our correspondent's opinion, we are still, under the circumstances, forced to repeat that the Georgia law, as it now stands, is an insult to the profession of that State, and should be modified or repealed accordingly.—ED.].

Antiseptic Dissecting Instrument Cases.—The latest announcement is that for an antiseptic dissecting instrument. Of course it is intended that the "subject" shall be duly protected against infection as well as the operator, for it is a bad rule that cannot work both ways. The utility of the measure, however, is on a par with the recommendation of a graveyard, to the effect that it was on high ground, was well drained, and that no case of malaria had occurred within its limits. In fact, it was a very desirable locality even for well people.

New Instruments.

A UNIVERSAL NASAL SAW.

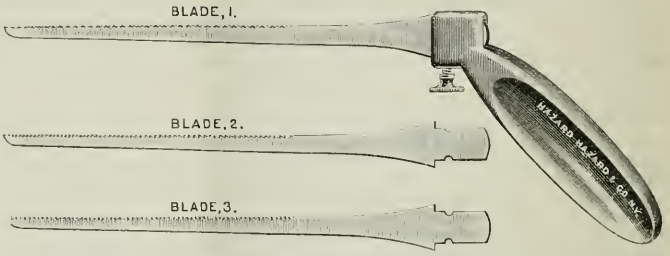
BY CHARLES A. BUCKLIN, A.M., M.D.,

NEW YORK.

THIS saw combines the advantages of similar instruments, obviates their defects, and represents the conclusions resulting from an extended experience.

The handle is of sufficient size to give one a firm grasp, which is important when the bony deformity is large. Being of aluminium, it is aseptic and light, notwithstanding its size.

The requirements for nasal saws are as follows: They must have the necessary length and strength. They must cut without springing the septum out of its normal position by bending. A properly made saw will not displace a deformity in the nostril before the section is completed.



These desired results are obtained by regulating the size, thickness, and shape of the saw teeth. I regret that many of the nasal saws in the market are not designed to meet the necessary requirements.

Thick, large, and improperly constructed teeth, short saws, probe-points, and double teeth, all defeat the ends aimed at in a nasal saw.

This instrument has three reversible blades, six inches long, containing three and one-half inches of cutting teeth.

Each blade is designed to overcome special difficulties. They are not hampered by probe-points, and may be rapidly withdrawn and re-entered through the cuts they make when hemorrhage or a change of saw makes it desirable.

I appreciate the generous acknowledgment of Dr. Bosworth in his paper before the Academy of Medicine, which was published in the MEDICAL RECORD, January 29, 1887, in which he stated that I was entitled to priority in the practical use of the nasal saw.

For the above, as well as meritorious reasons, I incorporate in an unaltered state, as one of the elements of this instrument, the saw-blade suggested by Dr. Bosworth, and designate it as Blade No. 1, or the Bosworth saw. This blade consists of perfectly cone-shaped teeth, thirty to the inch. It is made thin, and bending is avoided by dividing the cutting-power equally between both sides of the teeth.

Conditions are encountered where it is desirable to cut only as the saw advances. Blade No. 2 will meet these conditions. This blade would bend were it not for the fact that the teeth are thirty-two to the inch. They rake sufficiently forward to enable the finger to determine the "rake," as the teeth are drawn over it, while or the return stroke the release is complete.

This blade is very satisfactory for the following reasons:

1. With the head firmly placed against a head-rest, the most natural way to cut with a saw is toward the support.

2. In attempting to remove the inferior turbinated bone entire, the spring of its posterior end frequently causes other saws to bend sufficiently to defeat the operation, which difficulty is not experienced with Blade No. 2.

3. Deformities of the septum which terminate at their

posterior end in a delicate ridge will readily catch on teeth which cut on the return, thus springing the septum toward the saw. When this accident occurs a single stroke may cut directly through the septum. These dangers are also obviated by Blade No. 2.

Exceptional conditions may arise where it is desirable to use a saw-blade which cuts on the return stroke.

Blade No. 3. This blade is less frequently useful than either of the others. It can only be used on the turbinated bones in rare cases where Blade No. 2, from some accidental peculiarity in the formation of the bone, cannot be used. Peculiarities in the deformities of the septum may present exceptional cases where this blade will work better than the others. It is, however, liable to spring the septum in an undesirable direction, producing accidents already described. Still the instruments would not be universal without this blade.

I claim that this saw will remove the average bony deformity found in the nose in a more practical and satisfactory manner than any other appliance.

Hoping that operators will not trust the disinfection of a saw to any means less perfect than boiling water, I will leave the further application of the different blades to be determined by their practical experience.

THE OLD AND NEW IODINE BOTTLE.

By GEORGE E. ABBOTT, M.D.,

NEW YORK.

EVERY gynecologist is well aware of how many bad words he is responsible for when the cork of his iodine bottle becomes extracted in his instrument case, destroying his satchel and rusting his fine instruments, or when it upsets on his patients' carpets, leaving its indelible stain as his unfortunate autograph.

After trying all sorts of bottles and stoppers, I have found the following avoids all these annoying accidents.

Fill the bottle selected with absorbent cotton; pour in the tincture iodine to complete saturation; then pour out all that will readily drain away.

One now has plenty of iodine in a very safe form. Any application thrust into the cotton-filled bottle will be immediately saturated, for painting the vagina, or external work. Yet the bottle may be carried safely in satchel, or upset on the carpet, etc.

I hope this method for a "new iodine bottle" may save the instruments of others, and be of as much convenience and saving to them, as it has been to me.

This plan may also be adapted to other medicines as pyroligneous acid, carbolic acid, or any other material used for applications and liable to spill.

19 EAST SIXTY-FIRST STREET.

A UNIVERSAL ASEPTIC JOINT.

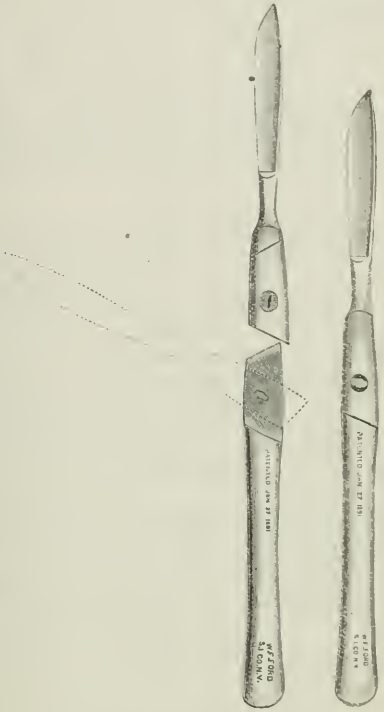
By SIDNEY YANKAUER, Medical Student.

NEW YORK.

MODERN "pocket-case" surgery has long felt the want of aseptic instruments, most notably of the scalpel. In how many cases thoroughly aseptic pocket instruments become a useful desideratum is made evident by the large demand for such instruments, and by the variety exhibited in the shops.

The object of my invention, which has not, I think, been hitherto attained, has been to produce a scalpel which, when put together for use, shall be of the same shape and size as the fixed scalpel, without catches or knobs projecting from its surface, interfering with the operator's fingers, and liable to be displaced; without springs or bolts concealed in septic hollows; a scalpel whose blades shall be readily and quickly changed, which shall be firm and, above all, thoroughly aseptic.

The accompanying cuts show the form of the scalpel. The blade ends in a flange which fits into a correspondingly sunk flange on the handle, and is secured thereto by a "French joint" and a diagonal shoulder. These parts are shaped in such a manner that every portion of the surface of the instrument is accessible to a towel or brush used in cleaning. Grooves and sharp corners having been avoided, adhering blood-clots can be readily removed with a sponge, and when immersed in an antiseptic fluid every part of the surface will be immediately touched by it. It is made of metal and can be boiled without damage.



When changing the blades the necessity of holding or adjusting a third piece is avoided, as the instrument consists of only two parts; and the blade cannot move while being used. Any variety of blades, including even dental and eye instruments, can be put on the same handle. The instrument is manufactured by the W. F. Ford Surgical Instrument Company.

333 EAST FIFTY-EIGHTH STREET.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 11, 1891, *to October* 17, 1891.

TAYLOR, ARTHUR W., Captain and Assistant Surgeon. By direction of the President, will report in person to Colonel John Mendenhall, Second Artillery, president of the Army Retiring Board, at Fort Adams, R. I., for examination by the board.

BEALL, GEORGE T., Captain and Medical Storekeeper. Granted leave of absence for one month.

EWING, CHARLES B., Assistant Surgeon, and Attending Surgeon at St. Louis, Mo. During the absence of Captain George T. Beall, will take charge of the medical purveying depot in that city.

GANDY, CHARLES M., Captain and Assistant Surgeon. Relieved from duty with Army Medical Board, to take effect on its final adjournment, and ordered to Fort Yellowstone, Wyo.

SUTER, WILLIAM N., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort McKinney, Wyo., and ordered to Fort Grant, Ariz. Ter., for duty.

MCVAY, HARLAN E., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Mackinaw, Mich., and ordered to Fort Wingate, N. M.

BENHAM, ROBERT B., Captain and Assistant Surgeon. Relieved from duty at Fort Hamilton, N. Y., and ordered to Mount Vernon Barracks, Ala., for duty.

GLENNAN, JAMES D., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Riley, Kan., and ordered to Camp Oklahoma, Oklahoma Ter.

IRELAND, MERRITTE W., First Lieutenant and Assistant Surgeon. Relieved from duty at Jefferson Barracks, Mo., and ordered to Fort Riley, Kan.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 17, 1891.

MAGRUDER, A. F., Surgeon. Ordered to the Boston.

DIXON, W. S., Surgeon. Detached from the Boston, and granted leave for two months.

MARSTELLER, E. H., Passed Assistant Surgeon. Ordered to special duty at Baltimore, Md.

DRAKE, N. H., Passed Assistant Surgeon. Detached from the Albatross, and granted leave for two months.

WIEBER, F. W. F., Passed Assistant Surgeon. Detached from from the Pensacola, and ordered to the Albatross.

BRADLEY, GEORGE P., Surgeon. Detached from Naval Hospital, Chelsea, Mass., and ordered to the Receiving Ship Wabash.

BRAITHWAIT, F. G., Assistant Surgeon. Detached from the Wabash, and ordered to Naval Hospital, Chelsea, Mass.

BEYER, H. G., Passed Assistant Surgeon. Ordered to Naval Academy, Annapolis, Md.

The Influence of Diet on the Growth of Hair.—In the *British Medical Journal* for July 25th, Dr. E. D. Mapother says: "Several cases of shedding of hair after influenza have confirmed my opinion that diet has much to do with the production and with the cure of symptomatic alopecia. Hair contains five per cent. of sulphur, and its ash twenty per cent. of silicon and ten per cent. of iron and manganese. Solutions of beef, or rather of part of it, starchy mixtures, and even milk, which constitute the diet of patients with influenza and other fevers, cannot supply these elements, and atrophy at the root and falling of hair result. The color and strength of hair in young mammals is not attained so long as milk is their sole food. As to drugs, iron has prompt influence. The foods which most abundantly contain the above-named elements are the various albuminoids and the oat, the ash of that grain yielding twenty-two per cent. of silicon. With care these foods are admissible in the course of febrile diseases, when albumin is the constituent suffering most by the increased metabolism. I have often found a dietary largely composed of oatmeal and brown bread greatly promote the growth of hair, especially when the baldness was preceded by constipation and sluggish capillary circulation. Those races of men who consume most meat are the most hirsute. Again, it is well known in the zoological gardens that carnivorous mammals, birds, and serpents keep their hair, feathers, or cuticle in bad condition unless fed with whole animals, and the egesta contain the cuticular appendages of their prey in a digested or partly digested state.

Common Sense in Medicine.—A celebrated bishop, president of one of the most noted universities of this country, said to his class in divinity: "There are three things necessary for making a successful minister of the Gospel: first, a thorough, liberal education; second, the grace of God; third, common sense. The first may be obtained by earnest, diligent application to study; the second by prayerful intercession at the throne of grace, with a sincere desire for purity of heart; but unless you have the third born in you, may the Lord have mercy on your souls and the souls of your congregation." While common sense is an absolute necessity for any profession or vocation, I know of no one where it is more necessary or important than in the study and practice of medicine. If I were asked to define the term common sense, it might be difficult; but it will be sufficient for our purpose, at the time, to say that it consists in applying rational, simple rules of construction to the various theories of medical science, adopting and practising what can be measured by such rules, and rejecting those that are at plain variance and antagonism with them.—S. C. GORDON, M.D., Portland, Me., in *Boston Medical and Surgical Journal.*

Microbes and Carpets.—In our endeavor to be comfortable in this vale of tears, there is a tendency to overlook the elementary laws of hygiene, and in no respect, perhaps, more so than in the superabundance of curtains and carpets—these non-patented contrivances for hindering the free circulation of fresh air and for stultifying Nature's automatic arrangements for the deodorization and disinfection of our homes. Carpets are always objectionable when they are not designed to permit of easy removal for cleansing purposes without the necessity of turning a room topsy-turvy. In most houses the carpet only comes up once a year, by which time it is as full of microbes and accumulated filth as its interstices will allow. No wonder, then, if our rooms preserve a musty smell in spite of periodical opening of windows and vigorous sweepings, which only displace a portion of the dust to settle promptly elsewhere in some less accessible spot. Fixed carpets are even more objectionable and unwholesome in bed rooms, for there they absorb the fetid emanations of the night, and soak up various decomposable materials for future use. The ideal would be a polished wooden floor garnished with rugs in sufficient number to give an aspect and feeling of comfort, while admitting of easy exposure to the salutary influence of air and light. Rugs, carpets, and curtains ought to be frequently shaken and hung up in the fresh air if they are to remain sweet, not once a month or year, but twice or thrice a week, if not oftener. At this price only can we hope to deprive confined spaces of their native unwholesomeness, and the sooner housewives lay this maxim to their hearts and act upon it, the better.—*Hospital Gazette.*

THE ENLARGED PROSTATE AND ITS OPERATIVE RELIEF.[1]

BY E. L. KEYES, M.D.,

NEW YORK.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY: Surgical progress has moderated, and, we may hope, eventually will do away with, that reign of terror which has been so long maintained by the enlarged prostate; a reign truly of terror for the sufferer, who could look forward to no final relief except that offered him by the scythe of the grim reaper, and a reign of hopeless, helpless incompetency for the surgeon, as far as affording radical relief was concerned.

There is no ancient history of prostatotomy or prostatectomy. The very names are of modern coinage, and the acts they represent have only become justifiable surgical procedures within the last few years. The only notable recent literary productions that I need refer to are the several articles in the London weekly medical journals, which have appeared from time to time, detailing cases and operative methods at the hands of A. F. McGill, of Leeds, whose recent death we all deplore, and to whose investigations and successful operations modern prostatectomy owes its first serious real impetus in England and in this country; to the thorough pathological study of Watson,[2] of Boston, whose theoretical conclusions, however, have since been modified by practical experience, and to the admirable *résumé* of the whole subject, a year ago, at the hands of Belfield,[3] of Chicago, who succeeded in collecting a table of operations, at the hands of various surgeons at home and abroad, representing 133 cases, in 41 of which the prostate was attacked by the perineal route, and in the remainder by supra pubic incision. Lists of cases and single experiences are constantly appearing in the journals, sometimes containing valuable hints, but historically I think Belfield's essay covers the ground, and its appearance less than a year ago renders any new attempt in this direction at my hands a work of supererogation.

It need only be recalled briefly that, up to a few years ago, the prostate had no surgery except the surgery of emergency. Its abscesses were opened, its stones were removed, when detected; it was cut through when the bladder imperiously called for drainage; but this was about all.

Certain enthusiasts and visionary therapeutists, from time to time, then began to appear, advocating possible absorption of the enlarged prostate by the internal use of ergot or interstitial injections of ergotine, its shrinkage by electricity, electrolysis, electro-puncture, or, more notably, the internal electro-prostatotomy of Bottini, who still advocates and practises the method, claiming, up to December, 1890,[4] 57 cases with 2 deaths, 32 cases improved, 12, no benefit. This method is doubtless better than the blind internal median prostatectomy as accomplished by Mercier's emport-pièce, an operation which Gouley, of New York, has unsuccessfully attempted to reintroduce. Then Reginald Harrison, of London, thought he could postpone the evil day and retard the results of enlarged prostate by pressure systematically applied through the urethra with long, olivary, soft bougies. And again, another suggestion of Harrison's, puncture of a large prostatic lobe through the perineum, and the tying in of a solid tube for a long period, was hopefully referred to as a method of producing absorption. Yet none of these resources have gained permanent foothold in the profession.

Meantime at various hands progress was being made. The advantages of vesical drainage in advanced cystitis, advocated and introduced by Willard Parker, of this city, led to a number of operations on old men. A prostatic bar was often cut down, or a big lobe incised, at first without particular design, then as distinctly advocated by Harrison, for the purpose of introducing a tube much larger than the one commonly employed, and for the express purpose of straightening the prostatic canal and lowering its floor. In lateral perineal lithotomy also, long years ago, cases were reported in which the surgeon's forceps accidentally brought away, along with the stone, a large middle lobe, or his finger enucleated out of the lateral incision an interstitial fibro myoma; and after these operations it is narrated how, to the delight of the sufferer and surprise of the surgeon, the patient, perhaps for years before dependent upon the catheter, had suddenly again become capable in his urinary function and had so remained.

Yet these latter accomplishments were accidents, and did not constitute a surgical method, but out of them undoubtedly arose prostatotomy and prostatectomy—at first perineal, and later, after Peterson had revived the suprapubic route by the more rational approach above the pubic symphysis, where the eye can see and the hand perform much more capable work than through the bloody and straightened perineal channel.

To-day prostatotomy and prostatectomy are accomplished surgical facts and splendid additions to our resources in that class of grave vesical disorders found so often in the best ranks of the community, late in life, in those who use their brains rather than their muscles and lead sedentary lives.

Yet the indications for these operations are not yet fixed, although Belfield's analysis of his tables, and McGill's generalizations, have advanced the decision.

The questions on which I shall ask for discussion tonight, giving of course my own impression after narrating my cases and personal experience, are: 1. When is perineal prostatectomy to be preferred to the suprapubic operation? 2. What condition of prostatic or vesical disease, or both, justifies radical operation, and should it be done early or late? 3. How much of the prostate should be taken away?

Prostatotomy, as an adjunct to vesical drainage, has been so generally recognized as a proper concomitant of the latter operation that its consideration need not detain us; nor need we consider that new form of operation, lateral prostatectomy, performed by dissecting off the rectum from the prostate and peripherally slicing away its lateral lobes without opening either the urethra or bladder. This operation was suggested theoretically, after cadaveric research, by Dittel, last year; but aside from its manifest inability to cope with median prostatic overgrowth, it has been tried and found wanting this year by

Küster,[1] who reports three successful cases, stating that the operative manœuvre was not difficult, the patients were contented with the operative effect and could urinate at will, but that in each case a small urinary perineal fistula was left behind. My cases, 11 in number, 3 perineal and 8 suprapubic, are briefly as follows:

Perineal Cases. — Case I. — X——, aged fifty-four. Uses catheter every two or three hours and relies upon it; has practically done so for several years; median hypertrophy suspected; stone found. Perineal incision, April, 1874. Phosphatic stone removed; small third lobe twisted off. Voluntary urination returned and remained until death, several years later.

Case II.—X——, aged sixty-five. Painful and very frequent urination night and day. Catheter finds resid ual urine, but its use fails to afford relief to the straining and dribbling, which is almost incessant. In February. 1883, perineal incision and forcible removal by twisting of an outstanding section of the right lateral lobe as large as the last joint of the thumb, weighing eighty grains. Much relief followed, but no cure. Intervals increased to between three and four hours, night and day. Bladder does not empty itself entirely. Patient is a drinker.

Case III.—X——, aged sixty-six. Recurrent violent hæmaturia; moderate peripheral prostatic enlargement, a little residual urine, prostatic bar; blood demonstrated by examination to come from the prostate and just in front of it. Perineal section in June, 1891; third lobe upon the bar incised in **V**-shape and twisted away. Its weight is thirty-four grains. Result, September, 1891: Health and strength excellent. Urination free. No recurrence of hæmaturia.

These three cases, and another under my charge, in which, however, my assistant, Dr. Fuller, did the operating, all recovered and were successful in securing relief of pain and freedom of urination—in Case II. voluntary urination until he died, several years later; in Case I., where the catheter had been solely relied upon for four years a cure of persistently recurring profuse hemorrhage; in Case III., and the right of way to voluntary urination in Dr. Fuller's case. My reasons for selecting the perineal route were, in the first two, non-acquaintance with the suprapubic method at the time. Had I the cases to-day I should attack both of them above the bone. In the third case the old gentleman was feeble, bled profusely, and I believed I had to do only with moderate peripheral hypertrophy and a granulating bleeding bar, from which I expected to take a **V**-shaped piece. I found a small pro jective lobe along with the bar, and removed the lobe by the **V**-shaped incision. In the fourth case there was perineal stricture as a complication, and the entire operation was done through the perineum.

The perineal operation, it seems to me in looking back over the cases, is suitable for election only under three circumstances: 1. Great feebleness of the patient where the main indication is to get drainage and save life, and in which the prostate is not very hard and not very large in its lateral lobes. Here drainage can be well borne, as a rule, through the perineum, and with a moderately long finger a projecting lobe, median or lateral, may be made out, unless the patient be fat and the perineum deep. When such lobe can be located with a Blizzard knife inserted flat upon the finger, a converging incision into the prostatic substance may be made in **V** shape on each side of the offending projection, and then the latter may be wrenched away with long-curved forceps.

This was the method I adopted in two cases. In the other I simply twisted off a largish pedunculated third lobe. All the patients were thin and their bladders easily reached by the finger through the perineal incision.

I think in future, in any similar cases, I shall pass a double-woven silk ligature over the projections by means of these long-curved dressing forceps with holes drilled near the tips of the blades, which I have had made for this purpose, but have thus far only used through an incision above the bone. I believe that with such an instrument, after a **V**-shaped incision had been made, including the offending lobe, or even a **V**-shaped piece of the bar, a double silk ligature could be placed and a small écraseur worked, with the forceps still holding the ligature in place, until the latter had embedded itself well into the prostatic tissues; then the dressing-forceps and écraseur could be removed and the latter reapplied upon the same ligature, held in place by their embedment; and I think that such a method of removal will be better than the rougher tearing out process that must otherwise be resorted to, in order to get the **V**-shaped segment away. Such tearing brings away sometimes too much tissue, as a long unnecessary strip of mucous membrane.

The **V**-shaped incision cannot be very accurately made at the bottom of the perineal wound. It cannot in any hands be accurately carried to a point, and some tearing is necessary.

I used this forceps to apply ligature in my third suprapubic case. It worked admirably, except that one of the silk strands gave way. The fibrous enclosing membrane, and I judge sometimes also the prostatic substance, is too hard to be cut through by silk, and I intend trying flexible steel wire through the perforated forceps upon my next case.

Deep prostates and very large, hard, lateral lobes, if the prostatic tissue be very dense, as it may well be, are not suitable sometimes even for simple drainage, prostatotomy, or much less prostatectomy by the perineal route. I have seen the tube partly collapsed or even squeezed out by the clasping action of two large-sized lateral lobes. These cases, I believe, should be approached—even if it be only for simple drainage, the patient's condition precluding more radical measures—they should be approached, I repeat, by the suprapubic and not the perineal route.

Suprapubic Prostatectomies.—Case I.—X——, aged sixty-five. Condition deplorable; constant pain; urination at intervals of two hours day and night; urine full of blood, albumin, and casts. Vesical atony with five ounces residual urine; both lateral lobes large and hard, small lateral internal projecting lobe; small phosphatic stone. Operation, September 15, 1890. Stone removed and small projecting lateral growth snipped away with curved scissors. Attempt was then made to enucleate the large lateral lobes with the finger, but it was impossible. Neither the finger nor the curved scissors could make the least impression on the dense fibrous mass. The finger was passed under the mucous membrane of the prostatic sinus, and externally under the prostatic fibrous sheath, but by no effort could any portion of the dense mass be loosened or torn away. I then thought of the rongeur, and always carried it afterward. but I did not have one with me, and was therefore obliged simply to cut away the soft mucous covering surrounding the vesical orifice, and to mince the edges and bar between the lobes by repeated wrappings with the scissors points. The operation was therefore technically unsatisfactory, in that the dense large lobes were left about as big as before the opera tion.

Result, a year later, September, 1891: Voluntary urination without pain, vast improvement in general health, catheter never necessary. This doubtless due to the removal of the outstanding lobe, but the five ounces atony persists as before and makes urination frequent, unless the catheter be used occasionally to drain away the residuum. In short, the patient is like many another with atony who has never been operated on. The misfortune here is that not having a rongeur I could not take out enough of the bar or of the dense lateral lobes to do the operation properly.

Case II.—X—— , aged seventy. Relies entirely upon catheter, which has frequently to be passed, but the passage is attended by difficulty and pain. He had been divulsed about a year before, and an enormous sound introduced, without advantage, by his physician. No chill or disturbance followed this operation. The cystoscope

[1] Munchener Med. Woch., April 14 1891.

showed a small third lobe. The urine was clear, no blood, no pus, no albumin, no casts, and an operation was urgently demanded on account of local distress. I cut this gentleman in March, 1891, and pinched off his small third lobe with the rongeur.

Result.—Half an hour after the operation he had a chill, and practically a total suppression, from which he never rallied. I consider that the result was one of those unusual cases of pernicious urinary fever. It was, of all the prostatectomies I have done, the most trifling in extent, and the result was more unexpected than if it had occurred in any of the other cases.

Case III.—X——, aged sixty-six. Atony; eight ounces of residual urine. Patient not dependent on catheter, but not at all relieved by it. Urinates every two hours by day, and twice at night. Prostatic sinus in free suppuration. Prostate peripherally large and possessed of a third lobe as big as a plum. All local measures unavailing. Moderate local hemorrhages occur constantly; life intolerable, and operation demanded.

April 16, 1891, I cut this gentleman, and removed his third lobe with the wire écraseur. I then snipped away the collar-like, bulging, urethral prostatic orifice, and with the finger easily broke down the soft prostate, shelling out two hundred and forty-nine grains of prostatic substance and a number of rounded distinct fibro-myomata, one of which was polypoid and was scraped out of the prostatic sinus, being soft and easily removed by the finger-nail. I had no occasion to use the rongeur.

Result.—In three weeks the patient was up, with the wound healed, and he left his house on the twenty-third day.

Examined in September, 1891. He is perfectly well, except for a trace of pus still in the first urinary gush, but disappearing. He empties his bladder in a full stream at an interval of between three and four hours. His atony has disappeared, for a catheter passed after voluntary urination gets nothing.

Case IV.—X——, aged fifty-nine. Has a large stone and median hypertrophy; relies on the catheter, which he passes sometimes hourly, then at longer intervals. Has been an invalid about four years, the last one being passed in bed. Urine like bean soup, thick with pus containing blood, casts, and albumin without stint. The patient was ready to die, and accepted operation without a murmur.

I cut him early in July, 1891, and removed a stone as large as a hen's egg, weighing seven hundred and forty grains. The third lobe was as big as the last joint of the thumb. I placed a double silk ligature over it with the dressing-forceps having dulled ends, and snared it off. Then I cut out a deep piece from the place where the stump grew, lowering the prostatic outlet considerably. The bladder was sacculated greatly.

This patient recovered promptly, and now has given up the catheter, urinates in a full stream, holds his urine from five to seven hours, and is a well man. He has gained fifty pounds in three months.

I operated on this gentleman more out of compassion for his sufferings than in the hope of saving him. I feared urinary fever and suppressions, and gave him, therefore, ten grains of diuretin every few hours after his operation. He had no chill, no suppression, a result so agreeable and so striking that I could not but attach some possible influence for good to the diuretin. I have used it in every major operation upon the bladder or urethra since this case, twelve in number, and have never had yet a chill or suppression since I began to use it, three months ago, although some of my cases have been desperately severe; there have been six prostatectomies, one suprapubic lithotomy in a fat old man, an intense diabetic, who got well, although his heart failed and his liver stopped for several days after the operation, yet the urine welled up as limpid as a spring through it all; one suprapubic drainage for vesical cancer; three perineal urethrotomies with guide, and two very severe ones without guide; one litholopaxy. One case only died, my last prostatectomy, at the end of the second week, but he died by exhaustion with a weak heart and an unhealthy wound. He had no urinary fever, and his kidneys did their work freely and uninterruptedly until his death.

Case V.—X——, aged sixty-six. Catheter life for six years. When I saw him he was using it every two hours. He was wasted to a shadow, with eczematous eyes and pustules over his body, putrid urine full of casts, albumin, blood, and pus; no appetite, dry tongue; manifestly in septic depression. I washed and disinfected him, got him on milk diet, and did all I could, with little effect except in reducing his sepsis and curing his pustules, as well as sweetening the urine. He lost twenty pounds during the winter. I cut him above the bone, July 17, 1891, and gave him plenty of diuretin, with salol, and constant vesical irrigation. I took out stones weighing sixty-three grains, and prostatic third lobe, and bar weighing three hundred and seven grains. There was no bad symptom. Recovery was uninterrupted but slow. The patient is now in the country, and has not answered my letter asking about voluntary urination. His bladder was completely atonied, and I shall investigate this point with interest. Whether his voluntary urination returns or not, his life was unquestionably saved, and in a double sense, because when I hesitated to operate upon him he told me calmly that if I declined to attempt to help him he intended to resort to the Roman remedy.

Case VI.—X——, aged sixty-five. Occasionally can urinate, but very often not at all; retention habitual and catheter constantly resorted to. Cannot sit for pain. His whole life is given up to efforts at urination; gets up every hour and a half at night. I cut this patient suprapubically on August 18, 1891. I thought before operating that he had prostatic stone, because a finger in the rectum made out a projecting, very dense, hard lump, bulging below his right prostatic lobe, and an acupressure needle passed into this lump through the rectum struck calcareous material. I found a small, horse-collar enlargement, with moderate bar and conical third lobe upon it. These I easily removed with scissors and rongeur. Then with the needle I demonstrated that the enlarged bulging right lobe was partly degenerated in a calcareous way—gritting as the needle entered it in many places—but that there was no true prostatic stone. I easily tore away with the finger and nipped away with the rongeur about half this right lobe, until I passed beyond the lateral bulge which it made within the prostatic sinus. The material removed weighs one hundred and sixteen grains. This patient was a little burned by using water too hot for the purpose to avert hemorrhages, and his recovery was retarded thereby, but he had no bad symptoms except loss of appetite and depression. The wound is not quite closed yet, although the patient has returned to his home in a neighboring city. Whether he can dispense with the catheter, therefore, I cannot now decide.

Case VII.—X——, aged sixty. In constant pain; urinates every two hours a day, four times at night. Has a minute calculus in the prostatic sinus. This I detect with the soft catheter while testing for atony, and I push it backward into the bladder. I then search with metal searcher and fail to detect the calculus. After the search, which showed third lobe and bar, so much disturbance followed that I determined to cut at once, which I did August 31st, above the bone, finding a gr. v. calculus, a prostatic bar, and large bulging lateral lobes, with collar like vesical orifice—weight sixty-three grains.[1]

In this case there was a little after inflammation of the space of Rhetzius, due to the use of a deep suture in the second week to draw the granulating surfaces together. The patient went home in his fourth week, but as the wound is still open I cannot report on the power of the bladder to empty itself absolutely.[1]

Case VIII.—X——, aged sixty one. In serious trouble; for eight years dependent on the catheter night and day; condition deplorable; constant pain and distress. This

[1] Both these patients reported October 25th. Both empty the bladder entirely, and are practically sound and free from pain.

gentleman I cut September 10th, removing four hundred and sixty-seven grains of stone, and one hundred and thirty-nine of prostate. He acted badly under the chloroform, which had to be used sparingly. He had no chill or suppression, no urinary fever or pyelitis, but his pulse intermitted greatly after the operation; he got hiccough at once, and obstinate constipation; his wound became and remained gray, never granulating; his temperature went up, then small shreddy sloughs appeared in the wound; his tongue became dry, his heart faltered, and he died on the fifteenth day.

Results.—Out of my eight suprapubic cases two died, one a most promising case, the last a very grave one. After Case II. all took diuretin freely, and salol, and in no case was there urinary fever, suppression, or pyelitis. Antiseptic irrigation and the usual precautions were always followed. In age the patients averaged sixty-four. The cases were not selected, except that all mild cases were refused operation and no desperate case was denied the chance, and of these several were so nearly dead when taken in hand that the operation seemed more like the short horn of a dilemma than an operation of choice or expediency. Suprapubic prostatectomy upon cases of this nature is of the first order in magnitude and gravity. In my opinion it far outranks nephrotomy, or even nephrectomy, in gravity. Even in the milder (seemingly milder) cases it is a grave resource, as my second case demonstrates, and I cannot agree with Belfield that it is proper to attack cases early, when their symptoms are not grave, with an operation the best statistics of which yield a mortality of $13\frac{6}{10}$ per cent.—McGill's statistics, 24 cases, show a mortality of sixteen per cent.—when the well-known chances of life with use of the catheter are so high, and when cases are on record like the German who lived forty-five years urinating only through a catheter, and Thompson's case of many thousands of insertions. I have had a case of twenty years' duration, and when the catheter is well borne an individual using it is not much worse off than a patient with hernia, who has to wear a truss. To suggest to such a patient an operation in his early career, with a mortality of at the very best one in eight, is like offering to kill a mosquito on a man's nose with a club. It is correct so far as the mosquito is concerned, but may be disastrous otherwise.

As to the power of restoring its contractibility to an atonied organ, my statistics lack value on account of the recent date of several of my operations. I should not have read this paper until a year from now, except on account of your President's solicitations.

Belfield's tables make, in 88 cases, 29, or one-third, restored to voluntary urination. Of these 26 were cases in which there was also calculus. In my eight suprapubic cases two died; in three of the others, although all are up and out, the wound is not quite healed; of the three remaining, Case I. was insufficiently operated on and his atony remains, although urination is natural and voluntary up to that point. Case III. had eight ounces of residuum and now empties his bladder completely. Case IV. also has entirely dispensed with the catheter and is functionally well.

Whether the others will lose their atony and empty their bladders entirely without catheter, I cannot now say. Of my three perineal cases, two emptied their bladders entirely after operation, one did not. Dr. Fuller's case still has the perineal wound.

Varieties in Prostatic Texture.—An important lesson taught by my cases is the variety in texture of the enlarged prostate. McGill states, and all operators advise, that the curved scissors be used first and then the prostate be dug out with the finger. Acting on this I operated imperfectly on my first case. Scissors would not cut it, except to cut away the projecting lobe. I loosened around it, but could not possibly dig out a shred with the finger or any instrument I had, so hard and tough was the prostatic substance. This suggested to me the rongeur, and with it I had great comfort. I am having some instruments constructed to cut out pieces of varying size and width; until now I have nipped and twisted away pieces with an ordinary rongeur, or crushed them with its cutting edge and then removed them with curved scissors.

Many prostates are soft and may be easily gouged out with the finger, both the soft ones, those containing interstitial tumors like Case III., and the very hard, calcified ones like Case VI. This could be torn easily by the finger into pieces of suitable size for removal.

The outstanding lobes can be removed with the wire or double silk snare (except that the enclosing membrane is sometimes tough and breaks the silk), or with galvanocautery or the tonsillotome, as Weir has suggested.

Salol and diuretin are the only medicines I use, with milk diet and Poland water. I have long since given up quinine in urethral and bladder surgery.

Hot-water irrigation sometimes stops hemorrhage, sometimes not. In the latter instance iodoform gauze may be stuffed down into the wound, or drawn like a big rosette into the urethro-vesical orifice upon a doubled silk thread passed through the urethra, and knotted over a pad at the meatus.

I have not used Albarran's tubes, but with their use the bladder might be packed antiseptically, and treated like an outside wound. Albarran and Lluria,[1] at the Society of Biology, July 4, 1891, report the successful experimenting of this retained urethral catheter upon a dog, and give Guyon's case of the young woman who wore them satisfactorily, after suprapubic section, for four days. The catheters are of soft rubber, made by Mathieu, and have a soft elastic bulb at the extremity which expands within the ureter—after introduction upon a stylet—and thus retains the tube.

Poirier, at this meeting, objected to injection of the ureters on the ground that substances so thrown in reached the renal vein without rupture of kidney-tissue.

I prefer the vertical to the transverse incision always, and in this operation, which yields so much hemorrhage, I prefer the open dressing. My method is to use one or two buried catgut sutures to attach the recti muscles, the yellow fat below the peritoneum, and the bladder-wall above its incision into one finely knotted mass, then to carry one end of the silk loop, on each side, that has been supporting the bladder during the operation, through the rectus on either side, and again to knot it, and then tie the two loops together under considerable tension, with a string passed across the sacrum, so as to hold the loops between the pelvic crest and the great trochanter on either side. This loop goes in over the skin through the rectus, through the bladder, thence up over the skin on either side, and the tension of the two keeps the wound constantly open. Continuous irrigation with hot boracic fluid may then be easily maintained night and day by means of an elevated jar of fluid and siphon-tube.

In final dressing, after some days, I find great advantage in keeping the patient dry from the use of the flat abdominal sponge constantly changed.

Amount of Tissue to be Removed.—A point that remains is the extent of tissue that should be removed. Belfield cites the notable failures that have occurred in his own and other hands in accomplishing the result aimed at, namely, voluntary urination—and perhaps also cure of atony may be added as an aim—on account of the physical impossibility of getting out a hard obstructive growth or interstitial tumor not infrequently found growing in the floor of the prostatic sinus, and not to be reached by the finger, or, as he thinks, in any way except by a combined perineal incision. I believe that with the rongeur or a similar instrument this objection no longer holds. The main object of the operation is to cut away the bar and depress the bladder opening into the prostate, so that the bas-fond may drain, and there may be no longer a suppurating pouch left the shut-in prostatic sinus.

[1] La Médecine Moderne, July 9, 1891.

This lowering of the vesical outlet and picking out hard growths in the floor or sides of the prostatic sinus, can be perfectly well done with the rongeur, but not with any other instrument yet in use. If all such obstacles are thoroughly done away with, the bladder outlet properly lowered, and the gross posterior bulk of the lateral lobes removed, I think it better for chances of life, and as good for chances of urination, to leave the greater anterior part of the prostate unmolested; and this can all be done above the pubis without any extra perineal incision.

The quantity of tissue removed, however, does not seem to influence mortality. In my most rapidly fatal case a piece as big as a pea was removed. My greatest amount was 307 grains in Case V., and recovery was uninterrupted, although the case was desperate and one of long standing.

The three greatest amounts removed that I know of are four ounces by Buckston Brown, in a man aged eighty-seven, who recovered, and something over two ounces each in two cases by McGill, one of which died.

The only argument in favor of early operation is that the longer the patients have suffered the greater seems to be the mortality, as J. William White, of Philadelphia, has emphasized; but this was to be expected, as such patients are older and more broken in every respect.

My conclusions are:

1. Prostatectomy is justifiable, and does what nothing else can.

2. The perineal operation is moderately less severe, but decidedly less reliable than the supra-pubic; it should rarely be preferred, unless there be urethral complications. In very feeble men it may still be elected.

3. The operation is not justifiable with present statistics if the patient can be comfortable in catheter life.

4. No physical condition of the parts or of the patient, short of a practically moribund state, contra-indicates operation. By it in desperate cases life is often actually saved, although the operation is a grave one and its mortality high.

5. With the rongeur—better than any instrument—the bladder outlet can be lowered, and polypoid or interstitial growths jutting into the prostatic sinus can be removed, and these points are more essential to a successful operation than is the taking away of a large portion of the prostatic bulk. The instrument next in value is the curved scissors, but the skilled finger is most important of all. Most of the work has to be done by the aid of touch, as the bleeding soon becomes free and renders visual inspection impossible.

6. Diuretin, perhaps, is of value when the kidneys are damaged. It certainly does no harm.

7. Chloroform alone, in my opinion, should be used as an anæsthetic for the kidneys' sake.

109 East Thirty-fourth Street, September 30, 1891.

THE INFLUENCE OF MATERNAL IMPRESSIONS UPON THE FŒTUS.

BY JOSEPH DRZEWIECKI, M.D.,

LATE PHYSICIAN TO THE UNIVERSITY CLINIC OF THE HOLY GHOST HOSPITAL, WARSAW, POLAND.

Although the belief in the influence of the maternal impressions upon the fœtus, which has existed long ago among all people, has found, and still finds, strong support from the greatest philosophers and most celebrated physicians, the subject has not yet found a proper place in science, being relegated to the region of delusions and fantastic fables. In the first place, the general belief in the influence of maternal impressions upon the fœtus found many opponents in the beginning of the eighteenth century, who began to prove that as between the mother and fœtus there exists no nervous connection; all such cases, principally collected by Sachs, Schroeck, Haller, and others, were either merely accidental or inherited. Afterward, however, the German writers made far weightier objection, namely, that every deformity, as the result of embryological defect, must be developed during a certain period of time, and for this reason cannot be the result of a momentary impression acting on the mind of the pregnant woman.

Nevertheless there have appeared from time to time, especially in the English and American papers, descriptions of cases seeming to prove the possibilty of such influence of maternal impressions upon the fœtus. And what still more deserves our attention is that many of these descriptions are given by men who are known as conscientious investigators and critical observers. It is sufficient to mention the works of W. S. Lowman,[1] T. Wetherby,[2] Thomas Hedman,[3] and many others, in which this subject has again been raised with great carefulness and criticism, and therefore we cannot yet regard this interesting and enigmatic subject as closed.

It is to be understood that by maternal impressions we do not mean the defects of development manifested by an arrest of the organism in the beginning of the embryologic state, but rather cases in which the psychical impressions are stamped on the development of the fœtus.

The following case, observed by myself, directed my attention to this question:

The wife of one of my friends, being in the second month of pregnancy, was frightened by the wound of her little son, four years of age, which he received on the forehead from a fall against an edge of a clothes-press. The wound, however, was not dangerous, but it alarmed the mother. In due course she was delivered of a female child, who had in the same place a red scar, showing the exact resemblance of that of her brother's.

Professor L Neugebauer described, in a Polish paper,[4] the following two cases, which I will cite in his own words: "In the Milan Anatomical Museum there is a specimen of a female child, who died at the age of three months. The skin of this child, from the head to the navel, is black-brown, and covered with hairs, and besides that there are spots of the same color in other places. It is curious that in the brain also are some dark spots. The mother of this child related to Professor Billi, previous to the birth of the child, and he personally communicated the facts to me, that she had once, while pregnant, looked intently for some time at a monkey that was being exhibited in the street." I must add that the monkey was dressed in short trousers, leaving his upper parts bare. "I, on my part," continues Professor Neugebauer,[5] do not doubt the possibility of the influence of maternal impressions upon the fœtus; my own son serves me as a proof of it. I once hurt my left leg on the inside by a thorn while bathing in a river. On my return home I dressed the wound. At the moment when I was cleaning it my wife, who was then in the first month of pregnancy, entered and was frightened by it. The boy, born in due course, has, in the same place where I have the scar resulting from the wound, a mark of the same shape and color."

Dr. Edward Garraway[6] relates the following very interesting case: "A lady of refined taste was in the habit of sitting before a group of statuary, with one little figure of which she was greatly enamored. This was a Cupid reposing, his cheek resting on the back of his hand. When her baby was born his resemblance in form and feature to the little Cupid was at once striking. On seeing him the next day in his cradle, I perceived he had assumed the precise attitude of the statuette—the cheek upon the back of the hand; and this position he invariably, and, of course, involuntarily, adopted during sleep, not only throughout infancy, but up to advanced boyhood, when I lost sight of him."

Dr. James Brydon [1] relates the following case occurring in his practice: "A short time ago I attended Mrs. C—— during her second confinement. After the child was born, the common question, Is it all right? was asked by the mother, and answered in the affirmative. Presently the nurse discovered that the great toe of the right foot was entirely wanting. The mother then related that, when she was in her fourth month of pregnancy, she dreamed that a rat had bitten off her corresponding toe; and so vivid was the impression that she awoke screaming, and narrated the cause of her fright to her husband, who corroborated her statement. The veracity of both parties is unimpeachable."

The following characteristic case is related by Charles F. Williamson: [2] "Mrs. D——, aged thirty, multipara, when four months pregnant, was opening the door of a shed in her garden, when a black-and-white collie dog pushed against her and ran away, having been shut up previously by her husband without her being cognizant of the fact. This made a deep impression on her at the time, and she continually, even to the time of her confinement, told her husband that her child would have a mole or be born disfigured in some way. So much did this prey upon her mind that her appetite failed, and she could not bear the sight of any animal, whether out of doors or inside the house. On September 26th I was sent for, and found a footling presentation, the right foot presenting. . . . I may say that when the right foot and leg were born there was great difficulty in keeping them warm, in spite of warm flannels. On examining the child the whole of the right thigh was covered by a mole from the groin to the knee, and entirely encircling the limb. The color was shiny black, and studded with long white hairs. There was another mole situated over the spine of the left scapula."

"About three weeks ago," writes John T. Hislop, [3] "I was called into the country to attend Mrs. M—— in her confinement. When I arrived at the house I found that the child had been born some considerable time, but the placenta had not yet been expelled. After removing this latter, I was shown the child, a well-developed male, which had evidently reached the full term, and could not have been dead many hours. The child's head was the extraordinary part, and exactly resembled a miniature cow's head. The occipital bone was entirely absent, the parietal bones only slightly developed; the eyes were placed at the top of the frontal bone, which was quite flat, and each of the superior angles of which was twisted into a rudimentary horn. The striking resemblance to, or, more correctly speaking, almost exact imitation of, a cow's head, was unmistakable. When, a few days afterward, I was able to speak to the mother on the subject, she told me how she had been terrified by a bullock when walking home from market during the second month of her pregnancy."

Dr. Charles W. Chapman [4] is of opinion that the whole available material we possess should be collected and definite conclusions drawn from it. He states the following case: "A lady, in comfortable circumstances, aged twenty-four, and of no marked emotional temperament, engaged me early in 1883 for her second confinement. The patient was exceptionally robust, and her little girl, then nearly two years of age, was in every respect healthy. The patient informed me that early in her pregnancy she had seen a man begging, whose arms and legs were all doubled up. The sight gave her a shock at the time, but she hoped no untoward effect would follow. I, of course, endorsed her hopeful view of her case, and urged her not to trouble herself any further. In due course I was summoned, and on examination found a shoulder presenting. The time of day being that in which all my medical neighbors would be out, I persuaded the patient to allow me to turn without giving chloroform. The operation was performed with some difficulty. The child was an anencephalous monster. The extremities were rigidly flexed, the feet almost sole to sole, and the fingers firmly clenched. The child could only have been dead a few hours. The mother was, of course, desirous of seeing her child, but I dissuaded her from this by assuring her that although this child was imperfect, there was no reason why she should not be more fortunate next time. The patient made a good recovery, and shortly afterward changed her residence. Four months later she became again pregnant, and unfortunately she frequently passed a man, who was a partial cripple, living in the same road. This circumstance revived the patient's fears; but she did not appear to be much depressed, and she was quite hopeful regarding her coming infant. The confinement took place at full term, and presented precisely the same difficulties as on the previous occasion. The child also was a counterpart of the last one, with the exception of the head, which was normal. After an interval of a few months my patient became again pregnant, and this time she was delivered of a strong and undeformed child."

It is impossible to cite all the cases published in the last few years. I have limited myself to the citation of some that seem to me to be more characteristic. I may add that the same facts are observed in the case of animals. Dr. Gray,[1] curator of the British Museum, showed at a meeting of the London Zoölogical Society, on February 24, 1864, a chicken, whose bill and feet perfectly resembled those of a parrot. These monsters were very often born in his hen house, and he explained them by the fright of the hen, caused by the cries of the parrot when the hen came near its cage.

My father, with whom I on one occasion spoke on the subject of maternal impressions, related to me that on his farm a peasant had a horse, whose face greatly resembled that of a cow's. As I was interested in this question, I took the first opportunity to see the animal, and must acknowledge that its face presented a striking resemblance to a cow, only the horns were wanting. The peasant was known in the whole village as the owner of the horse with a cow's head. I may state that in Poland the peasants keep the horses together with the cattle in the same stable.

Can we, in view of so many facts, affirm that maternal impressions have no influence upon the fœtus? To repudiate and deny so many facts, because they are in contradiction with the universally accepted opinion, is to affirm, in one's conceit, that all laws that govern nature are discovered and known.

It is true that no nervous connection exists between the mother and the fœtus, but does the absence of it exclude the possibility of the maternal impressions upon the fœtus?

If we only consider the following facts, we have no reason to deny the influence of maternal impressions: 1, That every idea, every impression, must be materialized, or, in other words, it is impossible without the work of nervous tissue; 2, that there exist many phenomena which cannot be explained by direct connection with the nerves, as, for instance, the action of one mind upon another at a distance; 3, that a certain impression or idea can influence the function of our tissues or organs, as, for instance, fear can produce many disorders in our organism, even the thought of a lemon can produce abundant secretion of saliva, etc. Besides that, the modern psychologists and physiologists believe that the fœtus, long before entering the world, is conscious of pain and physical satisfaction, and also gives expression to many impressions.[2] These affirmations of psychologists are

founded upon Luy's[1] experiments, which prove that the placing of the cold hand upon the walls of the abdomen immediately produces movements of the fœtus, and it is well known that the body is not a good conductor of warmth. It is also known that the light suddenly thrown into the eye of the mother, as well as a sudden noise, produces violent convulsive movements of the fœtus,[2] and Perez[3] states as a fact that a certain woman, experiencing great fear three months before the birth of her child, felt convulsive movements of the fœtus, and the child lived only a few months after birth, having very often, and without any external cause, sudden convulsive fits.

These are facts, proving that the fœtus may unconsciously, but yet truly, express maternal impressions. But how the external or internal world acts upon the souls, half-formed and perhaps already possessing certain indistinct self-knowledge, is a very hard question, which cannot be quickly solved. According to Luys,[4] the nervous cells are, during a certain time, in a state of vibration, produced by external impulses or impressions. If we agree with this writer, the question ceases to be obscure to us, or to exist in the region of imagination or fables. Besides that, it is known that deviation of the nervous fibre, during development, of even one-tenth of a millimetre will influence powerfully the structure and development of certain organs.[5] In consequence of this, an impression, be it continuous or accidental, received during fœtal life, influences the development of the brain and individual organs; therefore only one strong momentary impression, even in a dream, received by the mother and transmitted by her, is sufficient to produce afterward a run of changes in the development of the fœtus.[6]

On my part I am thoroughly convinced that different psychical and physical defects, which till now have been ascribed to inheritance, are in most cases the results of moral impressions derived from the surroundings of the mother. Naturally not every woman bears children with traces of her impressions. If it were so—as Buffon remarked—what strange creatures and strange characters we would see then. Nature did not furnish every man with the same susceptibility of nerves, and therefore the impressions have not the same effect upon everyone. We must, however, admit that strong and lasting impressions must undoubtedly have influence upon the fœtus.

It is a well-known fact that with animals the first male decides the influence upon the further offspring, so that the young ones descending from other fathers always show the traces of the first father.[7] Probably the first male produces strong impression on the female that lasts very long. With plants these facts have not been observed, as Mr. Knight[8] asserts. Probably also in the moral impressions of the woman lies the key to the secret why children of the same parents often entirely differ in character, temperament, capacities, appearance, etc. This difference, which can often be met with, stands in contradiction to the generally accepted theory of inheritance.

CONSERVATISM.

By C. B. MEDING, M.D.,

NEW YORK.

CONSERVATISM is a word of Latin origin, from *con* and *servo*—to keep, to guard, to preserve; popularly it means opposition to change, which is an ambiguous phrase, meaning either stubbornness, obstinacy, and eventually destruction, or, preference for the existing state. My paper is directed, then, first, against the use of the word conservatism, when the qualities carefulness or moderation are meant; second, against the use of the word conservatism in any sense as applied to medicine; third, for the use of the words carefulness and moderation, or their synonyms, for the reason that we are not in a position, as regards any single system or measure, to claim ordinary perfectness; and I hold that conservatism can only be of service in those arts, sciences, and trades where for long periods of time no radical change has been instituted.

There is no law so utterly without exception, there is no truth more absolute, than that which states change is universal. We cannot in any single field of observation or research find progress the result of immobility, and, more than this, let it be noted, the standstill is by comparison always retrogression. I believe progression to be the constant aim of nature. I have frequently been impressed with the fact that one's unspoken thought of to day is to-morrow spoken by another; you can all bear witness to the many so called coincidences of daily life; and this I consider the proof irrefragable of a rational supreme Being, that while it is permitted man to keep, or to give as original, the conclusions of his mental operations, yet, if he withhold, those thoughts are in no wise lost, but from other minds and lips will come forth as necessary to the knowledge of the age.

It is necessary to admit that progress may be impeded, and the admission bespeaks supreme mercy. Man possesses powers of obstruction, though not of destruction. It is too well known to need proof, however, that the most stubborn obstructions are made by the ignorant, since the objections of ignorance cannot be answered. Fools will ask questions sages cannot answer, and such questions are stubborn and harmful, because disregard of them is sure to be styled inability, while objections, unbiased, reasonable, and based on honest investigation, are healthful.

Every science and art seems to have had periods of advance, rest, and relapse; more than this, some seem to have reached, speaking temporally, perfection. For instance, in painting and sculpture the masterpieces of Angelo, Raphael, Titian, Correggio, Guido, Pissano, Rubens have never been surpassed, if equalled. In architecture the Ionic, Doric, Corinthian, Tuscan, Composite, Gothic, Norman, etc., are the models, and novelties consist mainly in new combinations. In music, Beethoven, Mozart, Bach, Haydn, Handel seem to have given every possible principle and style, leaving examples in every class which have not been excelled. Now, in each of the above we find the advance and perfection the result of an overwhelming interest, an exaggerated fashion, sometimes amounting to a mania. For example, the Church of Rome, in its zenith of wealth and power, became a vast building association, consequently a very nursery of the building genius. Next, these palatial temples needed adornment, and Rome became the mother of art; the world sent forth her geniuses, and to-day we call the works of that period masterpieces. Philosophy has lived almost entirely in the systems of Aristotle and Bacon; and mathematics and logic may be said to be in a state of rest.

You will notice, however, that a few sciences, though ever moving, have yet never gone beyond probability; astronomy, physiology, and medicine—meaning by this latter term the curing of disease and the preserving of health—are among these backward ones, and nowhere else in learning has fanaticism and superstition, backed by rigid conservatism, been so common. Witchcraft, once started, owed to conservatism its strength. For there settled upon the world at that time a kind of self-satisfaction, an unreasoning self-assertion. What is, is right; more than this cannot be; such was the doctrine of that age, and not a voice lifted against the darkness but was forever hushed. Such a state of affairs could not but

cripple to the greatest extent a study that has always been with the laity steeped more or less in mystery.

But, reasoning *a priori*, why may not this be the century of advance in medicine? Never before have anatomy, physiology, and chemistry made such strides, and every day opportunity for research enlarges.

"Learning," says Bacon, "has its infancy in beginning, its youth when luxuriant, its strength of years when solid and reduced, its age when dry and exhaust." It is in these last two periods that proper conservatism plays a part, for to this solid and dry state of learning can come no improvement, save only by a new birth, and such a birth should be acknowledged only after a self-won battle.

Now, medicine is yet as a whole in its infancy. The tendency having been to divide the subject into anatomical groups, diseases have followed, and specialties are now numerous, often inconsistent, and this has caused some branches to outgrow others. Surgery, for instance, has in this century reached a limit. I speak not of improvements, methods, or styles, but of extent. Every organ has been attacked: a spleen, a kidney, the limbs, portions of brain, liver, spinal cord, lung, stomach, lengths of intestine, etc. Still there cannot be a doubt but that the heart, liver, brain, stomach, bladder are without the domain of, if I may coin the term, excisive surgery. This is not due to a paucity of knowledge, but to the necessity of these organs to life.

I would not be understood as considering surgery perfected, there is room for improvement. It is, indeed, impossible to foresee the future of transplantation, implantation, and grafting, and I doubt not that some surgeons dream of endowing conglomerations of anatomical curiosities with life; but I feel that surgery has reached a limit for the present. To those who object I answer that history does not offer a single instance of an art or science that has not its period of quietude, caused seemingly by the stronger waves of the current of universal progress flowing in other channels.

The ordinary human life is the best example of nature I can offer; you will notice that each successive seven or ten years is devoted to the development of some one physiological part. Each system has its period of greatest growth, and in that period all parts not concerned simply exist.

The present day marks an important epoch in the treatment of disease. Dr. Koch looks forward to wonderful results; his continuation of an old idea looks forward to a universal principle; as yet darkness covers the field, still only a month ago a physician told me he was conservative, he did "not go much on this new thing." Alas, that, added to the difficulties of any innovation, there should be the spirit of "opposition to change!"

You cannot be conservative in your treatment of tuberculosis, of diphtheria, of the exanthems, of any disease, unless you believe in specifics, for there is no treatment to-day that is satisfactory. That man is very young who has not felt his helplessness at the bedside of dying humanity. He is only an idiot who can claim any treatment to be right beyond peradventure, and yet such is the opposition to change that in this day I have heard it said, concerning the use of electricity in stricture, by a man who admitted never having tried it, "I don't believe there is anything in it." That is called sitting on a man; well, I had rather such a man disagree with me than agree. That was conservatism as it is.

Conservatism may be the pass-word to perfection, or at least to constant excellence, but it is the barbed obstruction that pulls ever backward on the wheels of progress. It should mean moderation tempered by desire for the new and knowledge of and respect for the old. It is, however, most often a fatal clinging to the period of a man's student life, or to some single phase of experience.

Conservatism as a quality has injured the profession in general and in particular—the old and the new.

In general: It has lowered the physician from the high position of master and teacher to that of public servant; for it grew big with the child positiveness, and to-day we must often sacrifice our best determination for taste and memory, to pay for those dear old men who prescribed cures worse than the diseases.

It has, moreover, been the cause of that loss of popular respect which belongs to the physician. Public opinion since the days of Elizabeth has demanded a share of all knowledge; the last to yield to that demand was this profession, and to-day the public press and opinion is paying off the score. Patients know best to-day the effect of antipyrine, phenacetine, quinine, morphine, etc., on their system, and do not hesitate to tell it. In regard to this very latest study of Dr. Koch, the people have had the best information, and before doctors were willing to inject, people presented themselves for practice.

It has taught a certain disdain of old ideas and ways, together with a stolid scepticism toward the new. It has caused the loss, or at least the disuse, of many good medicines, for unlimited confidence in any one measure leads to its application in unfit instances, and consequently failure; and failure of a favorite means its death.

In another direction, this conservatism has flooded the druggists' shelves with a host of preparations of the same medicament. Dr. A—— will use none but Jones' hypophosphites; Dr. B—— wants Smith's; Dr. C—— must have Brown's; etc., *ad nauseam*. The druggist cannot keep so many, or perchance is out of one or the other; he substitutes. The doctor does not know the difference, there probably is none; the druggist takes courage, and substitution being successful, teaches not only fearlessness but also the very often unfortunate truth, the belief that the prescriber is a fraud.

Conservatism renders many consultations void and useless. It is not always jealousy that prevents the following of another's idea, but an honest, though unreasonable, love of one's own method.

It is this, I believe, that draws the often hard and fast line, the coldness and jealousy between the old and young. The youth, entering the field with new remedies and novel ideas, appears at enmity with those who cling conservatively to old notions and older medicines, and here it is detrimental, in that it dwarfs and impedes progress. That ancient medicine and old notion is not valueless, neither is the new remedy and later idea foolhardy; but they should come together, each should modify the other; by bringing the diamonds, experience and novelty, together we cut the perfect stone, rational improvement; let both be errors, is it yet not true that "the collision of errors elicits truth?"

One of the greatest, if not the greatest, surgeon in all Britain told me he considered the *doctor optimus* to be the American country physician, for, said he, his materia medica is revised by the experience of old women. There is no sadder part in our professional history than that telling of the general treatment of the young by the old. Outside of every other reason, the simple fact that the good of humanity is our life-work should lead to a helpful fellowship. Financially no man ever lost a dollar by allowing his knowledge to be helpful to the first honest comer, and that the old have much to learn from the young is acknowledged by every thoughtful man. A modification of any general method is a certainty. Be you old or young, single or en masse, your pet theories will be overwhelmed if they become to you universal remedies, or panaceas. But a gradual change, or rather a progressive development, will bring wisdom, while an overthrow causes failure. In any of the periods of craze, in the past, the opposition of the few rational men has been ignored; yet, my friends, how futile have proved the efforts of conservatives to keep alive their cure-alls, how vain in every case their stubbornness! But the reformers, whether individual or in sects, though they rose but to perish, have yet in their decay, cried victory! Hahnemann himself has modified the therapeutics of his successful enemies; Broussais stopped the fearful purga-

tion practised by his mockers; and to day hypnotism laughs at the scoffers of Mesmer.

If you will have conservatism, if you consider it applicable to your profession, then I fear only a millennium will bring the true application; for it should mean a wise moderation, a spirit of perpetual advance, a holding to the good, a fleeing from the bad, admitting that superiority is not the parent of invention.

It is not the most famous that do the greatest good, neither do the most successful advance the profession most.

A proper conservatism would, I hold, bind together the theorist and the practitioner. A physician should hold each remedy as a temporary aide-de-camp, not as the general of his life's whole warfare; present means should never become future extremes, and our minds should become imbued with the fact that morbidity, idiosyncrasy, and heredity do not offer a single opportunity for the application of a hard and fast rule.

Let us learn to hail him who presents a new idea as a student, not ignoring nor yet canonizing, but accepting and encouraging, remembering that even failure is a degree of advance.

We cannot in any wise be puffed up, for I believe the future of medicine to be beyond our comprehension. I believe progress in this art will be almost a revolution, but I believe that just so long as we allow each novelty to replace the present, just so long as we ignore the novelty and retain alone the present, just so long we obstruct. No profession offers such opportunities for the charlatan, no profession offers such opportunities for intellect. Let us then strive in every manner for the crushing of the former, and the immortal flight of the latter. Let us be out and out prudent, precise, and professional; free to refuse, free to accept; hiding behind no wall of custom, no buffer of conservatism, but alive to every advance; admitting weakness and imperfections, but demanding, mark you, demanding high and proper respect, for such is ever due a wise moderation.

MALIGNANT DISEASE OF THE VERTEBRÆ SIMULATING POTT'S DISEASE.[1]

By A. B. JUDSON, M.D.,

NEW YORK.

I HAVE seen three cases at least, in each of which malignant disease of the vertebræ was supposed for a time, by myself and other observers, to be Pott's Disease. The first case occurred in 1884. When first seen the patient, a boy aged four years and eight months, walked with a stiff gait and stooped carefully. Pain in the back and abdomen, the chief symptom, had been present two months or more. There was very slight, if any, projection, but I made a diagnosis of incipient Pott's disease at the first or second lumbar vertebra. When I saw him again, twelve days later, he had been in bed for six days, without motion or sensation of the lower extremities. A brace had been made for him by another observer, but the patient had been too ill to present himself for treatment. He still complained of pain in the back. Pulmonary and urinary troubles intervened, and death occurred ten days later. At the autopsy no caries was found. There were numerous sarcomatous growths springing from the dorsal vertebræ and some of the ribs. They varied in size, the largest having a diameter of two and a half inches. This growth had also invaded the vertebral foramina.

In 1885 I examined the second patient, a man aged thirty five. It was thought that Pott's disease might be the cause of certain symptoms which had led to a previous diagnosis of renal calculus. The patient was almost entirely disabled. He could with difficulty get upon or rise from the bed. Pain in the lumbar region and in the thighs was the chief symptom. Duration about one year. The normal spinal curves were unbroken. I eliminated Pott's disease, and suggested possible malignant disease. He died five months later. I am informed that morphine was used till the last, and that malignant growths were found attached to the vertebral column, and in the lungs and diaphragm.

In 1890 I applied a spinal brace in the case of a man aged forty two, who was paraplegic from supposed Pott's disease of two years' duration. At the eighth dorsal vertebra there was a slight but distinct angle. There was persistent fecal and urinary incontinence. It was thought best to try thorough mechanical treatment before opening the vertebral canal for the relief of the paralysis. No improvement being seen after ten weeks, the canal was explored by an operation which the patient survived but a few days. A sarcoma was found, the presence of which had not been suspected. Inspection was not carried farther.

Considering these cases, we are especially interested in the question of diagnosis. The two mistakes here reported would have been avoided if we had waited till kyphosis appeared; but an early diagnosis is always desirable, especially when the lower regions of the spine are in question, where the vertebral bodies are large, and where caries might exist a long time before the natural curves are broken. In none of these cases was there marked projection. In one the spinal curves were normal. In the others my notes contain the expressions: "Very slight, if any, projection," and "eighth dorsal vertebra shows a slight but distinct angle," words which may leniently be reviewed as intended to record suspected points in the vertebral column, rather than important diagnostic indications.

In two of these cases was present the paralysis which has caused this affection to be chiefly known in medical literature as "paraplegia dolorosa." This form of paralysis may well add, as happened in the cases reported, to the difficulty of differential diagnosis. Aside from points of neurological interest, the features of these cases, important to be remembered by us in future examinations, are the local pain and disability and the general reaction. All these patients were very ill, which cannot be said of most patients affected with Pott's disease. They all had severe pain and extreme disability in the back, which Pott's disease is so free from that, when we hear that there is pain in the back and spinal disability, the first thought is to eliminate spinal caries. It is strange, with the back virtually broken, as it is in Pott's disease, that pain and disability are not present and excessive. It is evident, however, that the recognition of these symptoms in a case of suspected Pott's disease should suggest at least the possible presence of an enemy still more intractable. These two affections are also different, in that in one the advance is insidious, while in the other the on set is alarming and quite in keeping with its implacable nature.

In brief, the chief diagnostic points are the following: 1, Deformity, present in Pott's disease, absent in malignant disease; 2, local disability, and 3, local pain, both absent in Pott's disease and present in malignant disease. I submit these thoughts as having some practical application, and would refer for a full account of this, happily not common, affection to the writings[1] of Dr. Edes and Dr. Amidon.

[1] Read before the American Orthopedic Association, Washington, D. C., September 24, 1891.

The Temperature of Drinks.—A writer in a German paper gives the following as the proper temperatures for different sorts of beverages: Water, 54°; seltzer water, and beer, 57° to 60°; red wine, 62° to 66°; white wine, 60°; champagne, 46° to 50°; coffee, 73° to 79°; beef-tea, 100° to 125°; milk, 60° to 64°; hot milk, 93° to 95°.

LAPAROTOMY FOR ACUTE INTUSSUSCEPTION.[1]

By B. FARQUHAR CURTIS, M.D.,

SURGEON TO ST. LUKE'S HOSPITAL AND THE NEW YORK CANCER HOSPITAL.

THE case which is to be reported is no triumph of surgery; on the contrary, it is one of those defeats from which we may learn sundry lessons of warning and guidance for the future. It is, moreover, worthy of record on account of some unusual clinical features rendering an exact diagnosis impossible, although it was evident that the only available treatment was immediate abdominal section.

Alfred N——, thirty years of age, married, a carpenter by trade, was admitted to St. Luke's Hospital on the evening of August 8, 1891. He had had pulmonary trouble for six months, and for three months had suffered from a diarrhœa, probably tuberculous in origin, with frequent attacks of colicky pain and vomiting. Three days before admission, just after he had eaten his breakfast, he was seized with an intense pain in the abdomen, followed by vomiting, and the pain and vomiting have persisted ever since. The pain was intermittent and colicky, not localized in any one part of the abdomen. The vomited matter was green at first, but had gradually become dark and assumed a fecal odor. Since that time he had had no stool, his diarrhœa ceasing at once, and he had not even passed any flatus. General abdominal tenderness developed, and he lay with his thighs flexed. He had been unable to retain anything on his stomach, and had passed scarcely any urine.

Examination on admission showed extensive phthisical changes in the right lung. The liver dulness extended one inch below the free border of the ribs. The abdomen was very slightly distended and tympanitic, and there was general tenderness, somewhat more marked on the right side than elsewhere. No tumor could be felt. Examination per rectum (by one of the hospital internes) was negative—the rectum was empty. The temperature was 96° F., the pulse 160, and small. The tongue was moist, but coated with a white fur. The patient was much emaciated and his face drawn and anxious. Under stimulation the pulse became 140, and the temperature rose to 100.4° F. The urine contained much albumin.

It was evident that one of two conditions was present—acute intestinal obstruction or subacute perforative peritonitis. The history of phthisis and diarrhœa, and the repeated attacks of pain, favored the latter view; but the slightness of the distention and tenderness after an illness of three days were decidedly against it. On the other hand, the symptoms did not correspond with the ordinary picture of intestinal strangulation, while the lack of abdominal distention seemed to exclude any form of obstruction without strangulation. Dr. William T. Bull kindly saw the case with me, and agreed that laparotomy was indicated in either condition, although it was extremely doubtful if the patient would survive the operation. Enterostomy would have been useless, because there was no accumulation of intestinal contents.

At midnight laparotomy was performed, with a median incision extending from the umbilicus to the pubes. A large quantity of clear straw-colored serum escaped when the peritoneum was opened, and there were no adhesions of any moment. I partly drew out a coil of small intestine in which a doughy mass could be felt, and, showing it to Dr. Bull, with the remark that it was fecal matter, let it fall back. There was so little distention of the bowel that it was difficult at first to say what was distended and what was empty, and it was not until the intestine had been exposed to the air for a few minutes that the difference between the coils above and below the point of obstruction became evident. The cæcum was found collapsed, and following the small intestine upward with the hand, about one foot above the ileocæcal valve the supposed fecal matter was again encountered, lying in a coil of gut in the pelvis, and when this loop was fully drawn out it became clear that there was an intussusception, forming a tumor about six inches long, so that at least eighteen inches of the ileum were involved. I had been deceived at first by the natural appearance of the sheath, by the softness of the apex of the intussusceptum, and by the ease with which it slipped back and forth in the sheath. The adhesions proved to be slight, and the only obstacle to reduction was the œdematous swelling of the intussusceptum; but this difficulty was overcome by firm compression with the left hand, while the adhesions around the neck were broken up and traction gently made with the right. About four inches of the bowel in the neighborhood of the neck was in poor condition, and there were two spots about an inch in diameter in which sloughing seemed almost inevitable; but the condition of the patient compelled me to close the abdomen at once, so the injured loop was wrapped in loose folds of iodoform gauze, and laid just within the abdominal wound, some of the gauze being brought out between the lips of the wound, which were lightly drawn together with temporary silk sutures, the idea being that in case of rupture of the bowel the intestinal contents would readily find their way out of the abdominal cavity; while if the gut did not rupture, the gauze could be removed in two or three days and the wound closed by secondary suture.

The patient rallied a little, and had a movement of the bowels, proving that the gauze had not caused obstruction by its pressure, but he died, as was expected, five hours later.

The autopsy showed tubercular ulceration of the intestine, but no tumor or other cause for the intussusception was found. The sloughing portions of the intestinal wall were the bases of ulcers, the pressure not having been severe enough to cause gangrene where the wall was healthy. There was nephritis.

This case is interesting in several respects. In the first place, there were none of the pathognomonic signs of intussusception—the frequent stools of blood and mucus, with tenesmus, and an abdominal tumor, so that we excluded that form of obstruction from consideration, although the history of the sudden onset of constipation in the course of a diarrhœa suggested it at once. The lack of distention of the bowel, even after three days of complete obstruction, is also noteworthy and is in favor of the theory of v. Wahl, who claimed that distention only occurs in those cases of acute intestinal obstruction in which there is at the same time some interference with the circulation of the blood in the affected bowel, for the circulation of the implicated gut was very slightly disturbed in this case, and probably no gangrene would have occurred if the intestinal wall had not been weakened in certain parts by the tuberculous ulceration.

One point of very great interest to me was the fact that the bowels acted before death, proving that the gauze which had been packed around the injured loop, similarly to the method employed by Hahn in resection of the bowel, had caused no obstruction by pressure or by traction. This is a welcome demonstration, for the expedient of wrapping gauze about a point where perforation of the bowel is to be feared, and drawing the abdominal wound together over it with temporary stitches is likely to prove useful in many cases of intestinal surgery.

But perhaps the most important fact in regard to the operation was the comparative ease with which the reduction of the intussusception was effected, giving another example of the truth that the adhesions and other pathological changes may be very slight even in intussusceptions of some days' duration; in fact, they have been found absent after several weeks. On the one hand, this should encourage operation, even when the case is not seen in the first twenty-four hours; while, on the other, it should warn those who feel inclined to wait upon nat-

[1] Read before the Surgical Section of the New York Academy of Medicine, October 12, 1891.

ure's method of cure by sloughing of the intussusceptum, against putting trust in the formation of adhesions as a protection against perforation and peritonitis. It should be noted, however, that in some cases the adhesions have become so strong in twenty-four hours as to render reduction impossible without injury to the bowel.

This case is only another illustration of the slowness of the profession in general to recognize acute intestinal obstruction and to take the only available means for its relief—operation. If the physician who had charge of this man for three days had promptly referred him to a surgeon, the patient would probably have been saved, even if the operation had been performed only twenty-four hours earlier, an estimate which would have allowed the physician forty-eight hours in which to make his diagnosis. It is true that the exact lesion present in this case was obscure, and even at the time when he was seen by us there was still room for doubt whether it was intestinal obstruction or perforative peritonitis, while there was scarcely a single symptom of intussusception. Nevertheless, it was clear that nothing but laparotomy could give the man a chance, and this fact must have been evident very early. I am not insisting upon this in order to blame the physician who had charge of the case (for the delay may have been the fault of the patient), but to emphasize the point that in spite of all that has been written and spoken upon this subject in the last few years, and in spite of all that has been gained by this discussion, the medical side of our profession are still reluctant to accept the theory that surgery offers a chance for cases of intestinal obstruction or peritonitis, for which there is otherwise no hope. Even when the truth of this claim is theoretically admitted the physician is apt to be too slow in acting upon it, and thus allows the patient to become exhausted by his sufferings, and lets slip the only opportunity of saving him.

Some years ago I was asked to see a case of chronic intestinal obstruction from a carcinomatous stricture high up in the rectum, in the medical wards of St. Luke's Hospital, and as the man was still in fair condition advised delay. A sufficient movement of the bowels was obtained and he improved, and I was not called to see him again until eight days later, when I found him in collapse, with an immensely distended abdomen. An artificial anus was made, but the patient expired in a few hours. The bowels had not moved for three days, but the house physician, doubtless made over confident by his previous success, and expecting every day to get a passage, failed to call me before the sudden collapse of the patient rendered it too late.

A few months since, a colleague was watching very closely a case of intestinal obstruction of a rather chronic type, in a female patient, due to adhesions from a laparotomy performed some time before. He was called out of town, having left word that if she grew worse I was to be summoned. In the afternoon of the same day she failed so fast that it was necessary to do a laparotomy at once, and I released a number of adhesions, but again it was too late, and the patient never recovered from the shock of the operation, which was a tedious one, as it was necessary to take some intestinal sutures to close one or two small ruptures of the intestinal wall.

These cases may serve to indicate how easy it is, even for good men who are on the spot all the time, to delay too long, and how dangerous delay is, even in hospital practice, where a laparotomy can be performed at half an hour's notice. In common with many other abdominal lesions, the fatal collapse may occur so quickly in these cases that even within that short interval the patient may fall from a favorable into a perfectly hopeless condition. Such operations are among the most disheartening in surgery, for the operator feels that he is merely making an *ante-mortem* examination instead of a *post-mortem* one. The truth is that in cases of abdominal lesions we cannot afford to count on the future even for half an hour at a time, and we must never lose sight of the fact that even in the most favorable case of this kind the uncertainty is as great as if we were feeling our way along the brink of a precipice in a dense fog.

In spite of these difficulties the results of laparotomy for acute intussusception have improved of late years. I once had occasion[1] to collect 70 cases operated upon from 1873 to 1887 inclusive, in which the mortality was seventy-six per cent. I find that there are now on record 105 cases, with a mortality of seventy per cent.—a very encouraging improvement. It also appears that out of 65 cases in which the intussusception could be reduced only 38 died, a mortality of fifty-eight per cent.—among the children the mortality was sixty six, among the adults forty-seven per cent. Of 17 cases in which the affected bowel was resected and sutured only 2 recovered, both adults. Of 16 cases in which an artificial anus was made (with or without reduction or resection of the intussusception) 2 cases recovered, also both adults.

Results of Laparotomy for Acute Intussusception.

	Children.		Adults.		Age?		Total.		Mortality, per cent.
	Recovered.	Died.	Recovered.	Died.	Recovered.	Recovered.	Died.		
I. Intussusception reduced	15	29	10	9	2	27	38		58
II. Intussusception not reduced :									
a. Nothing done	..	5	..	2	..	..	7		100
b. Resection and suture	..	7	2	8	..	2	15		88
c. Artificial anus made : 1. After resection or reduction.	..	6	1	1	..	1	7		88
2. Without resection or reduction	..	1	1	6	..	1	7		88
Total	15	48	14	26	2	31	74		70

These figures show that prolonged operations are almost invariably fatal, and furnish another argument against delay, for that is the usual cause of the conditions which render operations difficult. Delay is also responsible for the high mortality in these cases, for nearly all the patients are recorded as being in very bad condition, or even in collapse, at the time of operation. Laparotomy, to give good results, must be performed as soon as systematic efforts to reduce the intussusception with rectal injections have been made without success. We must constantly bear in mind both sides of the shield—there is danger in performing laparotomy for intestinal obstruction, but there is also danger in postponing it until it must be undertaken as a last resort.

Clinical Department.

A SOAP-EATER.

By R. ELLIS, M.D.,

DANBURY, CONN.

I SHOULD like to place on record the history of the following case of a mania for soap-eating, which I believe deserves the coinage of the word sapessomania; or a mania for eating soap.

Mrs. J——, aged twenty-nine, consults me in reference to an irritable stomach of long standing. She gives the following details: When about three years of age, she first enjoyed a mouthful of bar-soap; so agreeable was the taste that she would eat it "whenever she could get it." When aged five years, her mother found her, spoon in hand, eating soft-soap with keen relish. As she grew in years, so did her yearning for soap—her playmates ate candy, but she preferred soap; her father brought home to the other children sweetmeats, but to equally satisfy her a piece from common bar-soap must be given. Until she was eleven her sapessomania continued. When awake she loved to handle it, and smell of it, and eat of it. When asleep she dreamed of soap. Often, to pacify her, a piece was given to her to hold in her hand to soothe her to sleep, when she continued in her imagination still to eat soap. At eleven her stomach burned her so that she stopped her habit, but still continued to love to handle and to think of eating the great delicacy.

When twenty-three, or twelve years after her last feast, an advertising agent left at her door a five-cent bar of bath-room soap, which pleased her so much that she ate it all in twenty-four hours. Since then she has eaten none, though there is always the desire to do so. To-day, did not her stomach forbid, the yearning to "eat some more" would be irresistible. Though she can no longer eat it, she still loves to handle it, she loves to use plenty of it in her housework and in her bath-room. The smell of it is still sweet to her nostrils, and the thick suds she delights in remind her of the days gone by, never to return. Strange to say, she cares only for the coarse bar-soap—fancy soaps she never uses. Personally she is of nervous temperament, yet evidently a woman of much self-control. She asserts that her mania is as strong to-day as it was years ago, though she has tasted soap but once in eighteen years. Despite her statements, however, I believe she is still eating the little amount of soap which her irritable stomach will allow her.

A SUCCESSFUL CASE OF INTUBATION.

By H. S. McCONNEL, M.D.,

NEW BRIGHTON, PA.

EARLY in the morning of July 8th I was sent for to see a four-year child who was suffering from diphtheritic croup. It was about two hours before I reached the residence, and an aunt of the child said it was unnecessary for me to come in as the attending physician had just left, saying nothing more could be done, and that Howard was dying. I went in, however, and took O'Dwyer's tubes with me. Found the little patient lying on his back, head retracted, cyanotic, extremities cold, unconscious, and unable to swallow; but he had a good strong pulse. The physician in charge, Dr. E. W. Shuts, was recalled and we proceeded to intube the larynx. The child made no resistance until the tube was partially inserted, when he struggled so violently for breath that it was immediately removed, and with it came a large piece of membrane. This gave him instant relief, and in a few minutes he swallowed some whiskey and water. We now concluded to wait for the symptoms to again become urgent before making another attempt. In exactly two hours a No. 3 tube was successfully introduced, the string brought out through the mouth and fastened to the ear. In the evening the boy wanted his playthings. For the first forty-eight hours we fed him through a tube, after this by placing him on an incline, his head the lowest point. In this position he took all the nourishment he required with perfect ease. He improved rapidly, and on the fourth day, all the membrane having disappeared from the pharynx, the tube was removed, having been in the larynx just ninety-five hours. In removing the tube the string attached to it was passed through the fenestra of a dull uterine curette, and the latter then shoved back against the tube, the string being held tight; the curette was then raised and the tube slipped out easily. The child progressed favorably and rapidly toward recovery. That he would have died without the operation there can be no question, and it is equally certain that tracheotomy would have failed because of poor nursing. We desire to report this case, that country practitioners can see that it is possible for them to perform this operation. The instruments used are the property of the Beaver County Medical Society, the said society having voted to purchase a number of instruments that are expensive, and not frequently used. This case is its first purchase. This is very wise, as it makes it possible for many physicians to familiarize themselves with operations that they would otherwise be unable to, owing to the costliness of the instruments.

GUNSHOT WOUND OF THE RIGHT LUNG—SEPTICÆMIA—RESECTION OF A RIB—RECOVERY.

By Drs. HANSON and COE,

MISSOULA, MONT.

WILLIAM H——, aged thirty-two, policeman, while attempting to make an arrest January 14, 1891, was shot with a 45-calibre revolver, the bullet entering in the middle line of the body, about one and a half inch from the lower end of the sternum, passing backward and slightly upward, and emerging about three inches below the right axilla. It is said that the shock was quite profound, and the pain was severe; stimulants and morphine were administered hypodermically, and the patient was removed to his home. Hemorrhage was very slight, and there was no coughing or spitting of blood. About one month after the injury the case came under the writers' care. His condition then was as follows: Temperature ranged from 100° to 103° F., with frequent chills, profuse sweating, vomiting, loss of appetite, cough, hectic blush, and all the symptoms of septicæmia. Physical examination showed decided bulging of the right chest, especially at the lower portion, with dulness over the entire lung; respiratory murmur was made out only at the upper portions of the lung. Wounds of entrance and exit looked healthy, but while healed externally, it was evident that the condition internally was anything but good. It was decided to make a free opening at about the point of exit of bullet, break down all adhesions, evacuate the fluid and pus and thoroughly irrigate the cavity, making provision for free drainage.

The operation was performed on February 19th by Dr. Hanson, Dr. Parsons assisting. Dr. Coe administered the anæsthetic, which was done with great difficulty, as patient showed alarming symptoms if at all pressed, but was finally sufficiently anæsthetized to allow the operation to begin. A **V** shaped incision was made down to the ribs over the wound of exit, the flap was dissected up, and a large trocar and cannula plunged into the pleural cavity, allowing a quantity of thick fluid mixed with pus to flow out. The trocar was withdrawn, the opening enlarged, and the cavity explored with the finger, which broke down many adhesions and evacuated numerous pockets containing a dark substance, which was of the consistency of cream and rapidly solidified on cooling. Much débris, with bits of clothing, was removed, the cavity was thoroughly irrigated with hot wa-

ter, and a large perforated drainage-tube was inserted. Attention was now directed to the anterior wound. This was enlarged, and several pieces of dead bone with other foreign matter removed. The wound was thoroughly irrigated and a drainage-tube inserted. No communication was found to exist between the two openings.

The patient was in a low condition and reacted poorly, the radial pulse being barely perceptible. Free stimulation was resorted to, and the patient was surrounded by hot bottles, but for three days his condition was most critical. The stomach rejected everything, and all medicine and nourishment—viz., peptonized milk, wine of cocoa, and tincture of strophanthus—was given by the rectum; the wound was dressed on the following day, the discharge being very profuse. Thereafter it was dressed twice daily. Chloride of lime was used in the water for irrigating, as the odor from the decomposing lung was very offensive. The progress of the case from this time on to about April 6th was favorable, except that there was a very harassing cough for a week which was controlled with wine of tar and chlorodyne. It was evident, however, about this time that the cavity was not having as free drainage as was desirable, and that the patient was again showing signs of pus absorption, manifested by elevation of temperature, chills, exhaustive sweats, etc. It was decided that resection of a portion of one or more ribs was indicated, to give the freest possible drainage, and an opportunity to more thoroughly flush out the cavity.

The operation was performed on April 19th, by Dr. Hanson, Drs. Billmyer and Coe assisting. A semicircular incision was made down to the ribs, which were carefully exposed, and a section two inches long of the sixth rib was removed by means of the chain-saw and bone-forceps. All adhesions and gangrenous lung were again broken down, large amounts of pus, serum, and débris were evacuated, and the cavity was washed out. On examining with the finger the pleural cavity seemed to be (as far as could be ascertained) entirely empty of lung-tissue. A large drainage-tube was inserted, and the wound dressed. The condition of patient was much better than at the time of the first operation. The wound was dressed and the cavity irrigated on the following day, and twice daily thereafter for a month. Healing of the wound was remarkable, complete union being obtained on the ninth day, notwithstanding the fact that the wound was constantly and unavoidably bathed in the discharges. The discharge gradually grew less, and has now ceased entirely.

The anterior wound, however, shows that necrosis is going on in the lower end of the sternum, which is displaced downward and to the right. An incision will soon be made down to the dead bone, and same removed. The patient's condition is excellent. He has gained in flesh rapidly, at one time on an average of four pounds a week, looks well and strong, and expresses himself as feeling as well as he ever did. He returns to duty on the police force in a couple of weeks.

REMOVAL OF LIPOMA TUBEROSUM FROM A FEMALE SIOUX.

By Z. T. DANIEL, M.D.,

PHYSICIAN UNITED STATES INDIAN SERVICE, FORT BENNET, S. DAK.

INDIANS, as a rule, are not operated on by surgeons; they have a horror of being maimed or deformed, and are extremely wary of the knife; but now and then a case comes up for interference, when their confidence in the operator is well founded. On July 1, 1891, assisted by Drs. J. B. Ferguson, U. S. Army, and G. W. Wroten I removed a lipoma tuberosum from the axilla (right side) of a Sioux woman fifty-six years of age. Its short diameter was five inches; its long, eight inches. It was quite pendulous, and occupied the axillary space, and down on the posterior and inner aspect of the arm some five inches, and down along the border of the latissimus dorsi about four inches; the upper part of the tumor was projected into the lower part of the axillary space. Neither the brachial nor axillary arteries were involved, nor the basilic vein, nor the median or ulnar nerves. The growth was rather imbedded in the areolar tissue, immediately beneath the vessels and nerves mentioned. Its weight, about eighty ounces, was a source of discomfort to the patient, interfering with free motion of the arm, and causing neuralgia or pain in contiguous regions. She was easily anæsthetized with a mixture one-third ether sulph. and two thirds chloroform. One long incision, semilunar in shape, on the anterior aspect near its attachment, was made, the tumor was then dissected partly out. A similar or corresponding cut was then made on its posterior aspect opposite the anterior incision and the dissection completed. There were large blue tortuous veins traversing the tumor on its outer surface under the integument, and I expected much hemorrhage from the operation, but after the removal, and withdrawal of pressure from the axillary and brachial artery junction, to my surprise we found it necessary *to tie no artery*. I do not think more than three ounces of blood was lost; the incised vessels being capillaries and very minute. There was no supply artery to this large growth, that we could discover. The edges of the wound were sutured interruptedly with rubber adhesive strips between. All instruments, sponges, ablutions, hands of operator, sutures, and dressings were antiseptic (bichloride of mercury, 1 to 1,000. On the eighth day union had taken place all along the line of the incision, and sutures were removed, adhesive dressing reapplied and patient sent home. There was slight suppuration at one end of the incision on the side, but it continued for a short time only. Patient made a good recovery. There is a lesson to be learned from this operation, viz.: never fear a lipoma on account of its size or location; as a rule, they are simply masses of fat, occupying distinct boundaries, and usually implicating no important vessels or nerves, and are readily dissected out.

AN ILLUSTRATION OF HOW ATROPIA ACTS WHEN APPLIED TO THE CORNEA.

By JULIAN J. CHISOLM, M.D.,

PROFESSOR OF EYE AND EAR DISEASES IN THE UNIVERSITY OF MARYLAND, BALTIMORE, MD.

ONE of the accepted truths in therapeutics is, that mydriatics when applied locally to the eye permeate the cornea, mix with the aqueous fluid in the anterior chamber, and induce action in the iris by direct contact. This fact is capable of proof. When an eye has been brought under the influence of atropia with widely dilated pupil, wash thoroughly the conjunctival surface so as to remove all vestiges of the drug on the outer side of the eyeball. If the anterior chamber be now perforated by the point of a hypodermic syringe a few drops of the aqueous sucked up, and this liquid be dropped on the conjunctiva of a normal eye, dilatation of the pupil will ensue, as when a solution of atropia is instilled in the every-day work of the ophthalmic surgeon. It requires the presence of an aqueous secretion in an anterior chamber to produce a dilated condition of the pupil under atropia instillation. When an anterior chamber does not exist to retain or contain the alkaloid solution, no physiological action of the drug is found, notwithstanding the repeated application of the mydriatic. The following case well illustrates this fact in physiological therapeutics.

Miss M——, aged twenty-five, complained of impaired distant vision at the age of twelve, which developed into a case of conical cornea, with marked myopia, now excessive. Recently the apex of the left cornea has become cloudy and from its extreme prominence friction in lid movements is becoming uncomfortable. Vision in this eye is reduced to counting fingers at a very short distance. I suggested the following operation for the re-

duction of the bulging, viz., perforating the cornea by the actual cautery, a method which I have been practising for the past ten years. Under cocaine a large hole was burned through the centre of the cornea by the looped wire of an electric cautery. A jet of water two feet high followed the withdrawal of the perforating instrument, and was an index of the degree of tension of the eyeball. The application of the red hot wire was but for a moment, so as not to heat up the liquid in the anterior chamber to the injury of the neighboring tissues. Complete effacement of the anterior chamber ensued, with corresponding flattening of the cornea. The after-treatment was an instillation of a one per cent. sulphate of atropia, in a weak sublimate solution, three times a day. The object was to keep the margins of the pupil away from the corneal opening, so as to avoid adhesions. The next day, upon examining the eye, I found scarcely any scleral injection. There had been no pain. Little or no irritation had followed the cauterization. The draining of the anterior chamber was complete. The iris was in contact with the cornea throughout, except at the central perforation. Knowing that there must be some exudation to close up the orifice which I had made, I was anxious to keep the pupillary border of the iris away from the wound. Finding that iced applications of atropia had caused no visible dilatation of the pupil, I ordered six applications a day of this strong mydriatic. For ten days the wound remained open, the leaking of aqueous constantly going on. If the atropia solution was absorbed at all by the cornea it was washed out at once by the constantly escaping aqueous. The eye was carefully examined every day but no dilatation of the pupil was detected. It remained small and very little larger than the hole in the cornea. On the morning of the eleventh day from the time of operation I found the anterior chamber re-established, and the pupil enormously dilated. The moment the orifice closed so as to permit of the retaining of the aqueous secretion and the absorbed atropia the pupil promptly responded in excessive dilatation.

Progress of Medical Science.

Black Urine and Black Ascites. — Professor Senator believes that there are grouped under the name melanin several different pigments, which only have the black color in common. He has seen a case in which the dark brownish-red urine, turning darker on exposure to the air, gave the reaction with chromate of potash and sulphuric acid, but contained much indican, so that the coloration must be attributed to that. The autopsy showed the absence of melano-sarcoma. Moreover, bile derivatives may simulate the presence of melanin in the urine.. One ought to diagnose absolutely the existence of a melanotic tumor on the sole ground of the passage of urine which gives the chromic acid reaction, although all melanotic tumors occasion the passage of melanin in the urine. It is noteworthy also that urine may be passed by patients with melanotic growths which contains melanin but does not give the chromic acid reaction An advance in the differentiation of melanogen from indican has been made by the employment of bromine water or ferric chloride, neither of which act on indican. In a case of extensive melanosis Senator observed, besides melanuria, the effusion of a dark-brown ascitic fluid, from which after standing several days a black deposit fell. The pigment behaved with bromine water like that in the urine. The pigment in the urine was chiefly melanogen, but in the ascitic fluid it was melanin. In continuation of the data supplied by Miura, that after injection of hippomelanin into the abdominal cavity of rabbits, their urine contained melanogen in two cases out of four, Senator injected melanin from human melanotic tumors into the abdominal cavities of four rabbits, and found that the urine passed subsequently contained much indican, but no melanogen, and did not become darker with bromine water —*Birmingham Medical Review.*

Meningeal Angiomata.—Dr. Péan communicates a case of Jacksonian epilepsy, in which the attacks consisted of spasmodic contractions of the left arm and the muscles of the pharynx. The patient also suffered from very severe headache, and an operation was undertaken in the hope of finding some local cause for the pain and convulsions. They were found to depend upon an angioma in the membranes communicating with the superior longitudinal sinus, and Dr. Péan was able to remove the whole of it without loss of blood. The author says that he has been unable to find a record of any similar case which has been operated upon. The extra-cranial angiomata described by Nélaton and his pupils are quite different. They are visible and palpable, their only resemblance to the variety with which Dr. Péan had to deal being that they also communicated with the superior longitudinal sinus. In the case of intra cranial angiomata the prognosis is much more grave, from the fact that such a condition would be almost certain to give rise to symptoms of cerebral disturbance; but now that the cranial cavity can be opened, and the disturbing element removed, the prognosis is shorn of much of its gravity. The conclusions which Dr. Péan draws from a study of his case are as follows: 1. That besides extra-cranial angiomata there exists a variety of angioma situated in the membranes, and communicating with the longitudinal sinus. These are entirely intra-cranial. 2. These angiomata are simple—*i.e.*, they are composed of a loop of capillaries, dilated and tortuous. They do not present definite limits, but gradually become continuous with the neighboring vessels. Their chief feature is that they communicate with the longitudinal sinus by means of a dilated vein. 3. In contra-distinction to the extra-cranial angiomata, the intra-cranial tumors manifest themselves by symptoms of cerebral disturbance varying with the situation of the tumor. Such symptoms are especially localized pain and convulsions of the Jacksonian variety, and those symptoms, unlike similar ones which solid growths give rise to, vary with the position of the head, being augmented by flexion and by compression of the internal jugulars in the neck. 4. The prognosis is grave because of the effect which they produce on the brain, and because of the possibility of rupture and fatal hemorrhage, as was found in one case. 5. But those tumors are amenable to operation, and may be removed without greater risk than that of an ordinary operation.—*The Lancet.*

Caffeine in Pneumonia.—Dr. De Gempt urges the use of caffeine in cases of threatened collapse in various asthenic diseases, but especially in acute pneumonia, and cites several cases in which it was successfully used in conjunction with stimulants. He believes the drug indicated in the course of acute pneumonia when there is evidence of cardiac failure, such as rapid, irregular pulse with lowered tension. Should the pneumonia be of asthenic type, it should be used from the onset, and the earlier in the course of the disease it is used after asthenia develops, the better. In cases of this sort, caffeine, in doses of five to six grains four to five times daily, raises the arterial tension, diminishes the rate of the respiration and pulse, and lowers the temperature. Its action is prompt, but in urgent cases it had better be used hypodermically. It is advisable to continue it for a brief period after the febrile defervescence.—*Western Medical Reporter.*

Habitual Abortion.—Dr. Schuhl observes that when the cause of abortion is unknown, not only must the practitioner see that treatment suitable to all cases is carried out, but he must insist that the patient rests in bed at least during the days in each month of gestation which correspond to her normal menstrual epochs. Sometimes it is best to keep the patient in bed altogether till delivery. The causes of habitual abortion are very

numerous, but two unquestionably predominate. Retroversion is the first; the second is syphilis, whether maternal or paternal That disease sets up pathological changes incompatible with the development of the fœtus. Paternal syphilis must always be suspected when abortion is very frequent in a woman whose pelvic viscera are absolutely healthy. Hence Dr. Schuhl finds that mercurial inunction applied to the husband is much the best treatment for habitual abortion of uncertain causation. Apart from the fact that patients and their husbands do not always admit that they have had syphilis when they have really suffered badly from that complaint, and are not always aware that they may have passed through a mild form, it is certain that a strict specific treatment has sometimes been followed by fertility, even where all evidence of syphilis has been absent both in patient and husband.—*Annales de Gynécologie.*

The Treatment of Chronic Endometritis.—Dr. Skutsch divides this disease into two varieties. The first is the hemorrhagic form, known chiefly by frequent bleeding independent of menstruation, cancer, or fibroid. The second is catarrhal endometritis, where free discharge from the uterus is the most prominent symptom. The treatment of hemorrhagic endometritis is simple: the cervix must be dilated, the endometrium scraped with the curette, and all distinct fungous growths removed. Then cauterization is necessary. The operator must make sure that there are no small interstitial or submucous fibroids. Chronic purulent catarrhal endometritis is hard to treat Dr. Skutsch does not attach much importance to the distinction between cervical and corporeal endometritis, as in all cases of purulent discharge from the uterus both the body and the cervix must be treated therapeutically. Dilatation and irrigation of the uterine cavity are necessary. Laminaria tents are useful in practice, but they do not allow of free escape of injected fluids. He greatly prefers a blunt metal dilator. The injections are to be given daily. First, some water containing a three per cent. solution of soda is thrown up, to dissolve the mucus. Then the medicated solutions are to be used. A two and-a-half per cent. carbolic acid, 1 in 5,000 sublimate, or other antiseptic solution, is suitable for this purpose. Dr. Skutsch is not particular what antiseptic he uses. He thinks that the benefit is due to mechanical effects, the antiseptic being precautionary, so that the cure of the endometritis may not involve the establishment of worse pathological conditions. A simple catheter is far preferable to any complicated instrument for the purpose of injection; it allows more thoroughly of the return of the injected fluid. Recently he has dispensed with laminaria tents, and taken to dilating the cervix with iodoform gauze. Vulliet introduced this practice. Strips of ten per cent. iodoform gauze are introduced into the uterine cavity, and after injection more gauze is replaced. The introduction of the gauze is painless, and the patient can go about her duties. In obstinate cases the curette must be used in combination with the gauze and injections. Erosions usually disappear when their cause—purulent endometritis—is cured. If they persist, caustics must be applied. When the cervix is very much diseased, amputation or Emmet's operation may be required.—*Centralblatt für Gynäkologie.*

Observations on the Etiology of Diabetes.—Dr. Schmitz has recently published a paper on this subject, which is based on the study of 2,500 cases of diabetes observed by him. He distinguishes between idiopathic diabetes and melituria or melitæmia occurring in the course and as a complication of other diseases. Of the former he has seen 2,115 cases. He attributes great importance to predisposition, without which he does not think idiopathic diabetes can occur. Of his cases, 1,206 were males, 909 females. Idiopathic diabetes is very rare in childhood, rare in adolescence, but increases in frequency after the twentieth year. It is often overlooked in children. His cases, according to age, are as follows: From one to ten years, 10; from ten to twenty years, 75; from twenty to thirty years, 178; from thirty to forty years, 322; from forty to fifty years, 580; from fifty to sixty years, 678; from sixty to seventy years, 210; from seventy to eighty years, 60; from eighty to ninety years, 2. The author thinks idiopathic diabetes is rare in the inhabitants of Westphalia, Rhineland, and Bavaria, while it is common in Malta and South Italy, where it is as deadly as is tuberculosis in Northern Europe. But the Swedes are frequently diabetic, an observation confirmed by Swedish physicians, and especially by Professor Malmsten, of Stockholm. It is also common in Jews, whether of German or Italian birth. Cantani attributes the frequency of the disease in Malta and South Italy to the excessive use of saccharine foods. Dr. Schmitz admits that Maltese, Italians, Jews, and Swedes eat a great deal of sugar, and also suffer from diabetes; but all Maltese, Italians, Jews, and Swedes who eat a great deal of sugar do not become diabetic, while the disease is not common in many parts of East Germany and in North America, in spite of much sugar eating. Moreover, he has known diabetic Italians, Maltese, Swedes, and Jews who were diabetic, though they did not eat much sugar. He thinks that the liability depends on the race. He has observed hereditary predisposition in 998, nearly one-half of his cases. He has seen 5, 6, up to 8 or 10, and even 12 cases, in one family. These facts are all the more important, as many cases are no doubt overlooked. In many cases it was the brothers or sisters who were diabetic, and not the parents or grandparents. In these cases he thinks the predisposition was congenital but not hereditary.

Severe psychoses, especially melancholia, frequently leading to suicide, occurred in 428 diabetic families, while in the families of 263 diabetics there were no cases of diabetes, but one or more of insanity; also morphinomania, dipsomania, and onanism are frequent in diabetic families. He would add that the disease apparently occurs frequently in gouty and tubercular families. There can be no doubt that eating much sugar is injurious to diabetics, but the habit often long precedes the outbreak of the disease. In 641 cases for some time before the occurrence of diabetes there had been much sugar eating. He thinks if it had been excessive it might have given rise to gastro-intestinal catarrh, but not to diabetes. He was a long time in North America, and saw that the Americans are as much addicted to sweets as the Maltese or South Italians. In spite of this, and though they suffer much from dyspepsia, he has never heard that diabetes is very frequent.

The author regards care, worry, serious emotions, and nervous shocks as conditions which may aggravate existing diabetes or produce it. He has often seen anger or fear increase the quantity of sugar. After the great electoral campaign of 1887 many of his patients complained of increased sugar excretion and impairment of general health. He attributes this partly to the drinks, that would be numerous at such a time. But a great shock may profoundly affect a diabetic's nervous system without increasing his glycosuria, as in a case related where the death of an only son, the support of the family, threw a diabetic into a state of melancholia, but the sugar, which had disappeared, did not return. He refers to his paper on the communicability of diabetes, and he states that he thinks these cases must be merely coincidences. He says the etiology of idiopathic diabetes is so like that of tuberculosis that he wonders whether it also may be due to a micro-organism. Respecting his cases of secondary glycosuria, 155 occurred as a complication of gout, 128 in obesity, 17 in cancer, 16 in valvular disease of the heart, 12 in brain syphilis, 10 in morphinomania, 9 in liver cirrhosis, 9 in spinal cord diseases, 1 in waxy liver, and 1 in Addison's disease. Besides these, 6 occurred after a fall on the head, 4 after a blow on it, 1 after cerebral concussion in a railway accident, and 3 showed themselves in convalescence from typhus. He should call it melitæmia in disease of the pancreas if he could diagnose that condition.—*Berliner klinische Wochenschrift.*

SOME NEW STUDIES IN THE THERAPEUTICS OF TYPHOID FEVER.

AN interesting and novel study of the therapeutics of typhoid fever has been made by Drs. G. Rocque and E. Weill, of Lyons, France (*Revue de Médecine*, September, 1891) and by Professor Teissier of the same city.

The object of their investigation was to determine the effect of treatment on the elimination of toxic substances by the urine; the method consisting in determining the "coefficient of toxicity" of the urine in typhoid fever when the cases were not treated at all, and when treated by cold baths, or antipyrine, or naphthol. This toxic coefficient is obtained in the following way: The total urine of twenty-four hours is measured and filtered; enough of this is injected into the auricular vein of a rabbit to produce the death of that animal. The urotoxic coefficient is represented by a fraction, of which the numerator is the weight of the animal, and the denominator the amount of urine necessary to kill it. The figure used for the denominator, however, is the amount of urine secreted per kilogramme of the patient's weight. The normal coefficient is about 0.363 kilogr.

In typhoid fever this coefficient is always much increased, owing to the greater excretion of toxic products. This increase averages about .700, or double the normal. It is lowest at the beginning of the fever, and steadily increases (.560 to .800); it is quite independent of the fever itself, and also of increased secretion of urine. It lasts after the fever subsides, and continues throughout convalescence, or even longer.

In Lyons two methods of treatment prevail, that by baths—the method of Brand and Glénard—and that by antipyrin, according to the method of M. Clément, viz., the administration of seven to fifteen grains of antipyrin every three hours. The statistics of M. Clément are said to be *très belles*, and they have evidently weaned some of the Lyons physicians away from their baths.

The danger in typhoid fever, it is admitted, is not the fever; but it is, according to the French view, the toxic substances which accumulate in the blood. This danger from toxæmia can be combated in two ways, either by increasing the amount and rapidity of the elimination of the toxines, or by lessening their production. Four cases were submitted to the bath treatment and their urotoxic coefficient carefully taken. The amount of liquid drank was also measured.

The observations showed that under the baths the urinary toxicity increased steadily and enormously, so that the coefficient is increased to five or six times the normal. At about the tenth day it remains stationary, and in a few days begins to descend, so that by the time the fever ceases the toxicity of the urine is at the normal. The cold bath, then, does not lessen the production of toxines, but it is a powerful stimulant to their excretion.

Two cases were treated by antipyrin. In these it was found that under this drug the urinary toxicity promptly fell below normal, and continued so while the antipyrin was given. The coefficient sometimes fell below .200. However, as soon as convalescence began, and the antipyrin was suspended, the toxicity promptly rose to three or four times the normal, and so continued for a considerable time. Thus it appears that antipyrin does not lessen the production of toxines, but simply prevents their elimination.

Professor Teissier's observations, made in a similar manner with naphthol, showed that it lowers the elimination of toxines both during the fever and during convalescence, hence it had really a specific action in lessening the production of poisons.

If any general induction can be made from these striking but somewhat limited series of experiments, it would be that a combination of naphthol and cold baths would be the ideal treatment for typhoid from an antitoxic point of view; for the one agent would lessen the production of toxines, while the other would promote the elimination of those which were manufactured. The observations here quoted also tend to discredit the "bibulous" method of treatment which is advocated so strenuously by Lichtheim of Königsberg, and which has been adopted somewhat in this city. Dr. Valentini, the assistant at Lichtheim's clinic, gives typhoid patients two litres of milk, one litre of bouillon, and as much water as can be absorbed without producing disgust and repulsion. He also gives two hundred grammes of sugar of milk, dissolved in water, partly for its nutritive, partly for its diuretic action. Rectal injections of water are also given.

THE DISEASE THEORY OF INTEMPERANCE.

IT is a great pity that out of the discussion of the various phases of the temperance question so little practical good has yet come. The hostile forces, in a political sense, have ranged themselves along lines pretty well understood. In an ethical sense the lines of cleavage have now become quite distinct. If intemperance is a crime, say some, it should be punished by law. If it is a disease, say others, it should be so treated both by therapeutic agents, and, if necessary, by restraint, as is allowable in many diseases. The atmosphere of discussion has been somewhat cleared by the symposium in the current number of the *North American Review*, to which Drs. Hammond, Crothers, Carpenter, and Edson contribute. They all agree in the main, but work out their theories along somewhat different lines. All admit that drunkenness is on the increase.

It will be observed that all four of the writers lay particular stress upon the physical side of the question, and touch rather slightly on the moral. In this respect there will always be a great difference of opinion. Many

physical conditions which eventuate as disease are started primarily by man's knowingly violating the laws of health. The remoteness of the penalty lulls whatever scruples he may have at the time. But when the man is diseased we do not treat him on a moral ground, but on a physical. So drunkenness is in many instances a crime without any excuse or extenuation. As such it must be punished. As to the best method of punishment, there is a wide latitude of opinion. In many other instances, and perhaps far more than most of us realize, drunkenness comes from an environment not of the individual's own creating, and we should no more punish him therefor than we should for contracting phthisis or kidney disease.

In strong opposition to the general theory advanced by the contributors to the *North American Review* is the dissertation read some time ago, before the Connecticut State Medical Society, by Dr. W. G. Brownson, of New Canaan, Conn. He regards intemperance as "one of the many outgrowths of diseased conditions, mental, moral, or physical. . . . That it is in and of itself a disease is a misnomer. . . . Altered or arrested function is always followed by uneasiness or distress of mind or body, or both. There is naturally a desire for relief, and if the first thing that brings that relief be intoxicating drink, shall we name the disease alcoholic inebriety?"

Dr. Brownson boldly combats the truth of the statistics which go to show that residence in the various inebriate asylums is a permanent cure for a large percentage of the patients there treated. Along this line he comes into conflict with the statistics given by Dr. Crothers in the article in the *North American Review*. He quotes from the reports of the Scotch asylums, the Maryland State Hospital, and the Utica Asylum. These latter references are all to the effect that recoveries after institution treatment are only temporary. In the Scotch reports the authorities say: "It would not be easy to point out one single case of permanent and satisfactory reform." From Maryland the physician in charge of the dipsomaniacs says: "I do not know of a single case where a cure has been effected by confinement;" and the testimony from the Utica institution is in a similar vein.

Dr. Brownson calls attention to the fact that nearly all the literature in favor of the disease theory has been contributed by those who are interested in some inebriate home. They have, he alleges, drawn their conclusions from a few extreme cases, in many of which injury or insanity has been an important factor, and which, therefore, have been curable because due to a removable cause. From these insufficient data it is not fair to discountenance ordinary repressive or reform work, or the sacred rites of religion, as possible and probable measures for good.

The truth lies in a middle position between these two extremes. Undoubtedly many people have an hereditary tendency to drink. To punish them for alcoholic indulgence would be no more sensible or just than to punish a man who inherited weak lungs because he contracted a bronchitis or a pneumonia. On the other hand, there are many, and we believe the majority, who go into habits of drunkenness with their eyes wide open. They get drunk because they want to, and if they bring by their course disaster on themselves or misery on their friends, they should be regarded as law-breakers and not as diseased persons. Otherwise, as Dr. Brownson observes, we must not punish the drunken man for beating his wife, for he is diseased and has an "uncontrollable impulse;" and he very pertinently asks, "Will not the drunkards laugh at us for relieving them of penalties we impose upon the industrious sober classes?"

That reform in the penal management of drunkards must come, no one can doubt. But it must be along the lines where penal reform in general is being agitated, namely, the classification of offenders. At present all crimes are punished by fine, imprisonment, or death, and in the first two it is merely a question of degree according to the severity of the offence. And we do not believe that future experience will ever justify the unqualified dictum that intemperance is a disease.

THE MEDICAL PILGRIM'S PROGRESS.
